Abstract

A Josephson junction has the unique capability of transferring quantum mechanics rules to macroscopic systems and is at the same time a versatile component of all superconducting electronics with its key feature of carrying a dissipationless phase-driven current. Progress in materials science and nanotechnology consolidates expectations for a series of challenging applications, including the realization of multi-qubit quantum processors, while unconventional hybrid and high critical temperature superconductor Josephson junctions keep disclosing novel problems at the frontier of our knowledge. The diversity in Josephson junctions opens ‘horizons’. Much is happening and partly needs to be consolidated. Much remains to do.

Introduction

In these 50 years since its discovery (Josephson, 1962), the Josephson effect has played a key role for advances in physics both on fundamental aspects and applications. The key feature is a dissipationless current driven by a phase difference of the macroscopic wavefunction between the two superconducting electrodes. A Josephson junction (JJ) has thus the ability to manipulate and measure this phase difference transferring on a macroscopic circuit the quantum mechanics approach commonly applied on microscopic entities. Quantum tunneling takes place at a macroscopic scale in a JJ. A macroscopic superconducting circuit incorporating JJs will be described by a Hamiltonian built on the charge and phase operators. The states of the circuit will correspond to the eigenfunctions of the Hamiltonian associated to the specific circuit. The Josephson junction is an extremely versatile component of all superconducting circuits providing a series of unique properties and the required nonlinear behavior necessary for a wide range of applications (Barone and Paternò, 1982; Likharev, 1986). The Josephson junction is the main block of the superconducting qubit and thus of the emerging field of superconducting quantum computation engineering.

Josephson coupling is not confined to junctions using artificial barriers, but it extends to intrinsic junctions that may naturally build up across superconducting planes or grains or between coherent islands of size characteristic of the material. The Josephson coupling keeps being a formidable tool to disclose new fundamental physics (Barone and Paternò, 1982; Likharev, 1986; Tafuri, 2019). Since the discovery of high-temperature superconductivity in cuprates, for instance, Josephson junction-based phase-sensitive experiments are believed and have been used to provide the most convincing evidence for determining the pairing symmetry (Tsuei et al., 1994; Wollman et al., 1995; Van Harlingen, 1995; Tsuei and Kirtley, 2000). Hybrid systems offer special opportunities by combining the potentials of the superconducting electrodes with those of the barriers, as for instance topological materials, semiconducting nanowires, ferromagnets, graphene. These barriers and the related interfaces are considered as triggers of Majorana fermions, triplet superconductivity and fancy physics. We will give an account of the meaning of the Josephson effect, also

through its formalism, and of the methods used to demonstrate its nature and to establish its codes. These are indispensable references to be used in recent explorations on the Josephson effect. Much has to be expected in the future.

The coupling between macroscopic quantum systems and the equations of the Josephson effect

From tunnel barriers to transparent interfaces

Brian Josephson discovered that tunneling effect is not limited to quasi-particles and that also Cooper pairs can tunnel through a thin insulating layer (I) when the electrodes are composed of two superconductors S_R and S_L (Josephson, 1962). Cooper pair tunneling carries information on the phase difference of the macroscopic wavefunctions of the two superconductors. The Josephson effect is expressed by the two following equations, originally derived for an S_R -I- S_L junction:

$$I_s = I_c \sin \varphi \quad (1)$$

$$d\varphi/dt = 2eV/\hbar \quad (2)$$

where $\varphi = \varphi_R - \varphi_L$ is the phase difference between the two superconducting electrodes φ_R and φ_L , e and $\hbar$ are the electron charge and the reduced Planck constant respectively. I_c is the maximum critical current and depends on the temperature and the magnetic field. Josephson supercurrent survives as long as the macroscopic wave functions of the superconducting electrodes overlap in the barrier region (Fig. 1a).

The first tunnel Josephson junctions used soft superconductors as Sn, In, Pb, and thermal oxidation for the barrier. Later on, the "lead-alloy technology" was the first to use self-limiting sputter-oxidation process. A key advance was the development of devices

Fig. 1 (a) Spatial dependence of the macroscopic wave functions of the two electrodes in a Josephson junction in a 3-d and 2-d view. Different junction configurations: window-type geometry for a sandwich junction with (b) insulating or (c) normal metal or semiconducting or ferromagnet barrier. (d) Coplanar variable-thickness bridge; the barrier is grown before the deposition of the superconductor; the barrier can be a flake of graphene or of topological insulator (e) or a nanowire (f). The coplanar can also have an inverted structure where the barrier is deposited on the top of the barrier afterwards, as shown in (g). In (h) the scheme of a point contact junction is shown. In all these graphs we use grey/black for a superconductor, yellow for a metal or a semiconductor or a ferromagnet. Thin insulating barrier is in violet, while thick insulating layers are in green, and they serve to completely isolate the electrodes. The red arrow approximately indicates the current direction. In (i) scheme of microbridge. L refers to the length of the barrier, while W is the width of the weak link. Tri-dimensional view of a 001 tilt (j), 100 tilt (k) and 100 twist (l) grain boundary junction. In (j) it is also reported the bicrystal substrate, which in the most common technique determines the growth of the thin superconducting layer.

based on “rigid” superconductors as Nb, with the use of artificial barriers replacing the native Nb oxide barriers. Al turned to be the perfect material solution forming a natural, self-limiting, high quality, insulating oxide (Gurvitch et al., 1983). Other rigid superconductors such as NbN, Nb₃Sn, V₃Si and Nb₃Ge were later used (Wolf et al., 2017). The impact of high critical temperature superconductors (HTS) was also impressive for the development of activities on Josephson devices and to use these properties at unprecedented values of temperature and magnetic fields (Koelle et al., 1999; Tsuei and Kirtley, 2000; Hilgenkamp and Mannhart, 2002; Tafuri and Kirtley, 2005).

For a finite voltage $V \neq 0$ the phase φ varies in time $\varphi = \varphi_0 + 2e/\hbar V t$, as derived from Eq. (2), and an alternating current $I = I_c \sin(\varphi_0 + 2e/\hbar V t)$ appears with an angular frequency $\omega = 2eV/\hbar$. This is called the a.c. Josephson effect, and the ratio between frequency and voltage is given by: $v/V = 483.6 \text{ MHz}/\mu\text{V}$, of the order of 10^9 – 10^{13} Hz at typical voltages 10^{-3} – 10 mV. A direct manifestation of the a.c. Josephson effect is the presence of current steps at constant voltages: $V_n = nh/(2e)$ where $n = \pm 1, \pm 2, \dots$ in presence of microwave irradiation at a frequency ν_0 . The steps are the direct consequence of an interaction between the a.c. Josephson current and the applied microwave signal. These steps first observed by Shapiro (Shapiro, 1963) are commonly reported as Shapiro steps. The a.c. Josephson effect can be also derived from the very general arguments of spontaneous breakdown of electromagnetic gauge invariance (Weinberg, 1986; Anderson, 1997). The high precision predictions about superconductors, and for the a.c. Josephson effect the frequency of the alternating current in terms of the fundamental constant e/h , derive from spontaneous breakdown of electromagnetic gauge invariance in a S (Weinberg, 1986; Thouless, 1998).

The Josephson effect is not restricted to tunnel junctions (Fig. 1b), but it occurs in junctions with more transmissive barriers where the I layer is replaced by a metallic N layer (see for instance Fig. 1c). The Josephson supercurrent will flow in the resulting S_L-N-S_R structure as far as the thickness of the barrier is comparable with the coherence length $\xi_N = \sqrt{\hbar D_{\text{diff}}/(k_B T)}$ induced in the barrier (de Gennes, 1964) (T is the temperature and $D_{\text{diff}} = v_F \ell/3$ is the normal metal diffusion constant, being v_F the Fermi velocity, ℓ the electron mean free path and k_B the Boltzmann's constant respectively). ξ_N can be in some cases even of the order of a few microns. A barrier composed by a normal metal dramatically reduces the normal state junction resistance (R_N) and significantly modifies the junction capacitance (C). New physical “processes” replace tunneling, and they all fall in the category of effects induced by the proximity effect (PE), which will be specific of the junction configuration depending on the material, the type of barrier, the geometry, the boundary conditions. PE expresses the mutual influence between the superconducting electrode and the adjacent barrier layer, other than insulating (Clarke, 1971; de Gennes, 1964; de Gennes, 1966). The barrier is not limited to a normal metal but can be for instance a semiconductor, a ferromagnet, a topological insulator and so on, with novel effects related to the intrinsic nature of the barrier and of the interfaces. The various materials and their properties influence the geometry and the layout of the junction inspiring alternative ways of placing a barrier as reported in Fig. 1d–g, respectively. An accurate description of systems based on S/N interfaces can be also given in terms of Andreev reflection (AR) (Andreev, 1964), the microscopic process in which a dissipative electrical current is converted at an S/N interface into dissipationless supercurrent. AR is the scattering mechanism describing how an electron excitation slightly above the Fermi level in the normal metal is reflected at the interface as a hole excitation slightly below the Fermi level (Andreev, 1964). In Fig. 2a the energy representation of AR is sketched. The missing charge of $2e$ is removed as a Cooper pair. This is a branch-crossing process which converts electrons into holes and vice versa, and therefore changes the net charge in the excitation distribution. The reflected hole (or electron) has a shift in phase compared to the incoming electron (or hole) wave-function: $\varphi_{\text{hole}} = \varphi_{\text{elect}} + \varphi_{\text{superc}} \pm \arccos(E/\Delta)$, $\varphi_{\text{elect}} = \varphi_{\text{hole}} - \varphi_{\text{superc}} \pm \arccos(E/\Delta)$ where Δ and φ_{superc} are the gap value and the superconducting phase of the S respectively. φ_{superc} is equivalent to φ_L or φ_R used in all previous expressions. The macroscopic phase of the S and the microscopic phase of the quasi-particles are therefore mixed through AR. The Andreev-reflected holes operate as a parallel conduction channel to the initial electron current. The normal state conductance of the S/N interface is doubled for applied voltages less than the superconducting gap $eV < \Delta$ (Blonder et al., 1982). Blonder et al. (1982) (BTK) introduced the dimensionless parameter Z , proportional to the potential barrier at the interface, to describe the barrier transparency. This allows the continuous passage from the tunnel limit to a transmissive barrier since the barrier transparency is defined as $D = 1/(1 + Z^2)$. An exact expression for the tunneling current has been also obtained, using standard, many-body, nonequilibrium Green's function techniques (Arnold, 1985). The Landauer conductance expression has been extended to the case of an S-N interface through scattering matrix theory (Beenakker, 1997) $G_{NS} = 2e^2/(\pi\hbar) \sum_{n=1}^N t_n^2/(2 - t_n)^2$, where the t_n values are the transmission eigenvalues for the n channel, and N is the total number of channels. In a S_L-N-S_R structure multiple Andreev reflections occur (see Fig. 2b) (see below).

The modern era of Josephson devices is thus strongly influenced by the combined continuous progress in material science and nanotechnologies applied to superconductivity. These aspects are tightly connected. Progress in material science means new materials and new superconductors, and novel abilities in building interfaces and in the precise control of heterostructure in the growth process. Barriers of classical tunnel junctions (employing well-established low critical temperature superconductors (LTS)) benefit as well of the general technological progress and are designed and fabricated with unprecedented precision, opening the route to more performing devices. Advances in nanotechnologies applied to superconductivity is a necessary tool towards the practical implementation of Josephson devices using advanced materials, since they allow to suitably scale the size of the barrier and to handle pre-built barriers as for instance nanowires (NWs) and flakes. Hybrid junctions are an obvious consequence of the combined progress of material science and nanotechnology.

Another practical way to form a Josephson junction is through a point contact (Fig. 1h) or by creating a micro-restriction in a superconducting thin film (Fig. 1i). Scanning Tunnel Microscopy and atomic point contacts represent advanced versions of the original point contact technique (Wolf, 1985). For widths of the order of a few times the coherence length of the superconductor ξ_S , the microbridge will behave as a Josephson weak link (Likharev, 1979). This type of junction depends very critically on the dimensions of the microbridge and its characteristic lengths, ranging from a Josephson junction to a bridge hosting phase slip events

Fig. 2 (a) Energy representation of AR process: an electron excitation slightly above the Fermi level in the normal metal is reflected at the interface as a hole excitation slightly below the Fermi level. The electron is reflected as a hole with the same momentum and opposite velocity. The missing charge of $2e$ is absorbed as a Cooper pair by the superconducting condensate. (b) Energy representation of Andreev reflections in SNS junctions. (c) The d-wave OP symmetry configuration is reported for a 001 tilt GB for two generic misorientation angles θ_1 and θ_2 . Maximum coupling (maximum I_c) happens for lobes facing each other ($\theta_1 = \theta_2 = 0^\circ$) (d), while minimal coupling (minimal I_c) occurs for a lobe facing a node ($\theta_1 = 0^\circ, \theta_2 = 45^\circ$) (e). (f) “Corner” junction between an HTS d-wave electrode and an ordinary s-wave counter-electrode. (g) Andreev bands for different values of the D parameter: curve a $D = 1$, curve b $D = 0.8$; curve c $D = 0.5$; an opening of a gap in the Andreev band is evident in the presence of a potential barrier.

or Abrikosov vortex motion respectively. A kind of ‘phase diagram’ can be derived as a function of their dimensions (width W , length L) (Likharev, 1979). The Josephson effect only takes place for $L < 3.5 \xi_S$ independently of the width W (Likharev, 1979). Phenomena associated to phase slips ($W < \xi_S$) or to the motion of Abrikosov vortices ($W > \xi_S$) will take place for $L > 3.5 \xi_S$ (Likharev, 1979). In the limit of long microbridges, Josephson behavior substantially disappears in favor of a regime of strong superconductivity, where the critical current is controlled by standard depairing processes (Tinkham, 2004).

Josephson coupling can also take place at grain boundaries (GBs) and this property has been widely used to produce HTS JJs (Hilgenkamp and Mannhart, 2002; Tafuri and Kirtley, 2005). Any GB can be considered as the result of three fundamental operations as shown in Fig. 1j–l (Chaudari et al., 1988; Dimos et al., 1990): one electrode can be tilted with respect to the other electrode around the c-axis (001 tilt), or tilted around the a or b direction (tilt of the c-axis, 100 tilt) or twisted along the junction interface (100 twist). GBs can realize quite special atomically flat interface configurations. In HTS the d-wave order parameter (OP) symmetry generates quite unconventional features. In Fig. 2c the d-wave OP symmetry configuration is reported for a 001 tilt GB for two generic misorientation angles θ_1 and θ_2 (Hilgenkamp and Mannhart, 2002; Tsuei and Kirtley, 2000; Tafuri and Kirtley, 2005). Maximum coupling (maximum I_c) happens for lobes facing each other ($\theta_1 = \theta_2 = 0^\circ$) (Fig. 2d), while minimal coupling (minimal I_c) occurs for a lobe facing a node ($\theta_1 = 0^\circ, \theta_2 = 45^\circ$) (Fig. 2e). D-wave effects are visible in the whole class of HTS Josephson junctions in opportune conditions. In Fig. 2f for instance a “corner” junction between an HTS d-wave electrode and an ordinary s-wave counter-electrode is depicted. Here it is possible to measure the effects generated by the contemporary presence of two channels probing both lobes of the OP in the k_x and k_y directions respectively (Wollman et al., 1995; Van Harlingen, 1995). The angular dependence of the Josephson critical currents of c-axis tilt biepitaxial GB YBCO junctions has been measured in remarkable agreement with predictions based on d-wave OP symmetry (Lombardi et al., 2002; Tafuri and Kirtley, 2005; Kirtley, 2019b). On bicrystal GB JJs it is also based the powerful demonstration of the spontaneous generation of half-flux quantum vortices in the appropriate geometry for the cuprates, observed by a scanning SQUID (superconducting quantum interference device) microscope at the tricrystal point for an optimally doped YBCO (Tsuei et al., 1994; Tsuei and Kirtley, 2000). Finally in the layered crystal

structure of cuprate superconductors (especially in the most anisotropic compounds such as $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$), the current-flow of Cooper pairs from the CuO_2 sheets across the blocking layer is of Josephson type and, thus, a single crystal forms a natural stack of Josephson junctions (Kleiner et al., 1992; Kleiner and Wang, 2019).

In conclusions, we have never had so many different families of superconducting materials and so many different types of Josephson junctions as nowadays (Tafari, 2019), with so many fundamental open questions on their nature and on the prevalent mechanisms they exchange phase information.

More transparent barriers and the Josephson effect derived from Quasi-particle Andreev Bound States

A more transparent barrier, as occurring for barriers composed of normal metals, modifies the critical current-phase $I_S(\varphi)$ relation (CPR):

$$I_S(\varphi) = \sum_{n \geq 1} (I_n \sin(n\varphi) + J_n \cos(n\varphi)) \quad (3)$$

The d.c. Josephson Eq. (1) represents a particular case of this general expression. The I_n contribution depends on the barrier transparency D as a D^n power-law. The J_n vanish if time-reversal symmetry is not broken. The expression above may include effects related to possible anisotropic OP symmetry as previously mentioned (Tsuei and Kirtley, 2000). In this case I_n and J_n would depend on the angles θ_1 and θ_2 of the crystallographic axes with respect to the junction interface of the left and right electrodes respectively (Tsuei and Kirtley, 2000). The CPR is the major Josephson 'code' and is the input to calculate most of dynamical junction properties. Deviations due to higher harmonics occur in JJs with highly transparent barriers also at the meso- and nano-scale. In atomic point contacts single Andreev processes have been counted (Chauvin et al., 2007).

Quasi-particle Andreev bound states (ABSs) provide a natural framework to describe the Josephson effect in a large variety of systems traceable to $\text{S}_L\text{-N-S}_R$ structures. The electron obtains an extra phase of $\varphi_L - \varphi_R + \pi$ in each period (see Fig. 2b). The spectrum of the elementary excitations of a N layer in contact with S on both sides is quantized for $E < \Delta$. The expression of the bound state energy in the $\text{S}_L\text{-N-S}_R$ one-dimensional system in the short junction limit $L \ll \xi_N$ is (Kulik, 1969): $E = \pm \Delta \sqrt{1 - D \sin^2(\varphi/2)}$, as shown in Fig. 2g.

There is a general relation between the current through the Andreev state and the phase dispersion of the energy of the Andreev state, $I_S = \frac{2e}{\hbar} \frac{dE}{d\varphi}$ (Beenakker, 1992; Beenakker, 1997; Golubov et al., 2004; Lofwander et al., 2001). The d.c. Josephson current is a resonant effect, where the Josephson current flows through resonant Andreev levels. Surfaces may hybridize and form bound states in JJs, and Andreev reflection may lead to the formation of zero energy quasi-particle bound states, as for instance in d-wave superconductors (Hu, 1994; Sigrist, 1998; Kashiwaya and Tanaka, 2000; Lofwander et al., 2001). The existence of midgap states enhances the Josephson current at low temperatures. ABSs may have special features in hybrid junctions with unconventional barriers as for instance graphene (G) and topological insulator (TI). Differently from the usual case, where the electron and hole both lie in the conduction band, at a G/S interface for instance specular AR happens if an electron in the conduction band is converted into a hole in the valence band (Beenakker, 2008).

Essential parameters of a Josephson junction

The energy associated with the phase difference φ across the Josephson junction depends on the critical current I_c and is:

$$E = E_J(1 - \cos\varphi) \quad (4)$$

where $E_J = \Phi_0 I_c / (2\pi)$ indicates the Josephson energy, being $\Phi_0 = h/(2e) \approx 2.07 \cdot 10^{-15}$ Weber the flux quantum. This represents the energy stored in the junction in the superconducting state and comes from the kinetic energy of the charge carriers. The other relevant scaling energy of a JJ is associated to the charge Q which can accumulate on the capacitor C formed by the junction, giving rise to an electrostatic Coulomb energy $E_c = Q^2/(2C)$.

From the fundamental Josephson relations, it results that a change in the supercurrent modifies the Josephson phase, thus determining a nonzero voltage state. The junction thus acts like an effective nonlinear inductance

$$L_J = \frac{\hbar}{2eI_c \cos\varphi}$$

as it can be inferred by differentiating Eq. (1) and then using Eq. (2) (Barone and Paternò, 1982; Likharev, 1986). L_J has the unusual property of taking negative values in opportune intervals of the phase φ . A variable inductance is particularly relevant for quantum information manipulation (Clarke and Wilhelm, 2008; McDermott, 2009; Martinis, 2009; Oliver and Welander, 2013; Devoret and Schoelkopf, 2013; Kjaergaard et al., 2020). The maximum critical current I_c , the normal state resistance R_n and the capacitance C of the junctions define the characteristic energy scales of a JJ, the Josephson inductance L_J , the plasma frequency ω_J and the whole phase dynamics as it will be described in the next section. They also determine the spatial scale of the magnetic response of the junction by setting the Josephson penetration depth λ_J .

Properties of a Josephson junction and imprints of macroscopic quantum phenomena

Current-Voltage (I–V) characteristics: From the washboard potential to macroscopic quantum phenomena

In Fig. 3 we report I–V curves when changing the transparency of the junction barrier. The shape of the I–V curves are the very first fingerprints of the nature of a JJ. If we keep constant the cross section of the barrier, a change in the transparency implies a variation of the critical current density J_c . As a reference we also include an I–V curve with a characteristic downward bending (Fig. 3a) measured in microbridges, nanowires and HTS GBs with small misorientation. In a junction with higher J_c , as occurring for S–N–S JJs the bending is in the upward direction (Fig. 3b). This behavior is characteristic of low capacitance junctions and is commonly reported as overdamped regime. At lower values of J_c , I–V curves present hysteresis directly associated to the dielectric nature of the barrier and its capacitance (underdamped regime) (Fig. 3c). Switching events from the S to the R branch (see inset of Fig. 3c) as a function of the bias current are a manifestation of a stochastic process that is fully codified in switching current distributions (SCDs) (see below). Hysteresis can be incomplete with finite retrapping currents depending on dissipation (see for example Fig. 3d).

The Resistively Shunted Junction (RSJ) model, first introduced by Mc-Cumber and Stewart (Stewart, 1986; McCumber, 1968) gives an account of the I–V phenomenology in a variety of weak links (Barone and Paternò, 1982; Likharev, 1986). Representing the displacement current by a capacitor C and the sum of the quasi-particle and insulator leakage current by a resistance R , the current conservation for the equivalent circuit of the junction gives the following equation:

$$I + I_F = I_c \sin \varphi + \frac{V}{R} + C dV/dt$$

The noise source I_F is associated with its shunt resistance. In the following we will confine to the case $R=R_n$ (Devoret et al., 1985; Martinis et al., 1987; Massarotti and Tafuri, 2019a). By using Josephson relations, it can be transformed in:

$$\left(\frac{\Phi_0}{2\pi}\right)^2 C \frac{\partial^2 \varphi}{\partial t^2} + \left(\frac{\Phi_0}{2\pi}\right)^2 \frac{1}{R} \frac{\partial \varphi}{\partial t} + \frac{\partial U}{\partial \varphi} = 0 \quad (5)$$

where

$$U = -\Phi_0/(2\pi)(I_c \cos \varphi + I\varphi) \quad (6)$$

Fig. 3 At very high J_c , as occurring in microbridges and nanowires or in GBs with small misorientation angles (a), the I–V curves present a characteristic down-ward bending. (b) I–V characteristics of overdamped junctions. (c) I–V characteristics of underdamped junctions. This behavior is characteristic of tunnel junctions, and hysteresis is directly associated to the dielectric nature of the barrier. The switch from the S to the R branch is a stochastic process with a peculiar distribution. Hysteresis can be incomplete with finite retrapping currents and the presence of leakage currents (d).

Fig. 4 (a) Washboard potential for different values of the bias current for the standard sinusoidal $I_s(\varphi)$ relation. In (b) and (c) two dimensional projections for two different values of the current ($0.6 I_c$ and $1.1 I_c$) are given as examples. This phase representations correspond to the yellow points in the I-V curve reported in (d). The particle/phase overcomes the barrier in the washboard potential (e) by Thermal Activation (TA) or by Macroscopic Quantum Tunneling (MQT) (f), then it rolls in the running state. The SCs are reported as a function of temperature in (g). The standard deviation σ of the distributions are plotted as a function of the temperature in (h). T_{cr} signals the crossover between the TA the MQT regimes and is tuned by the magnetic field. Blue curve and red curve sketch measurements in absence and in presence of an externally applied magnetic field respectively. The magnetic field reduces I_c and thus ω_J , changing finally T_{cr} .

This equation describes the motion of a ball moving on the *tilted washboard* potential U (Stewart, 1986; McCumber, 1968) and allows a direct understanding of the junction non-linear dynamics. The term involving C represents the mass of the particle, the $1/R$ term represents the damping of the motion, φ the position of the particle and the average “tilt” of the washboard is proportional to I . A tridimensional view of U as a function of φ and I is shown in Fig. 4a.

When ramping the bias current I , the tilt of the energy potential increases and the height $\Delta U = \sqrt{2}/3 E_J (1 - I/I_c)^{3/2}$ of the energy barrier between consecutive wells decreases. For values of $I < I_c$, the particle is confined to one of the potential wells, where it oscillates back and forth at the plasma frequency $\omega_J(I) = (2\pi I_d / (C\Phi_0))^{1/2} (1 - (I/I_c)^2)^{1/4}$ (see Fig. 4b). For $I < I_c$ the average voltage across the junction is zero. When the current I exceeds I_c , the particle rolls down the washboard (see Fig. 4c); in this case a voltage appears across the junction (see Fig. 4d). Due to effects induced by thermal fluctuations and quantum tunneling, the junction may switch to the finite voltage state for values of $I < I_c$. The relative weight of these two escape processes depends on the temperature of the system (Kramers, 1940; Caldeira and Leggett, 1981; Devoret et al., 1985; Martinis et al., 1987).

A wide variety of I-V characteristics can be described through an opportune choice of parameters within the RSJ model and its variants. The McCumber-Stewart parameter $\beta_c = 2\pi I_c R^2 C / \Phi_0$ is a practical way to estimate the amount of damping of the junction (Barone and Paternò, 1982; Likharev, 1986). The strength of the friction can be also expressed through the junction damping parameter $Q = \omega_J R C$. Underdamped junctions have hysteretic I-V curves for $\beta_c > 1$ and are hence latching. For $\beta_c < 1$ overdamped junctions have non-hysteretic I-V curves and are non-latching. Apart from an obvious capacitive effect, the shape of the subgap currents is very indicative of the dissipative effects (Massarotti and Tafuri, 2019b), which are also strongly influenced by the environment, i.e., the circuitry connected to the junction. Both the nonlinear-Resistive (RSJN) model and the Tunnel-Junction-Microscopic (TJM) model attempt to include dissipative effects for a better account of subgap leakage currents (Scott, 1970; Likharev, 1986; Massarotti and Tafuri, 2019b).

The washboard potential offers a very intuitive picture even on macroscopic quantum phenomena (Leggett, 1980; Caldeira and Leggett, 1983). In the resistive state the particle is rolling down the washboard potential, it is escaping from a generic well by thermal activation following the very general Arrhenius law (Kramers, 1940) (Fig. 4e). In underdamped junctions and at very low temperatures, the dominant contribution to phase escape from the well is due to quantum tunneling (see Fig. 4f) (Caldeira and Leggett, 1981). A study of the distribution of switching events as a function of bias current and obviously of the temperature is the appropriate tool to quantify contributions to escape due to thermal activation (TA) and macroscopic quantum tunneling (MQT),

respectively. The SCDs (Fig. 4g) (Fulton and Dunkleberger, 1974) and their first and second momenta (the mean $\bar{I}$ and the standard deviation σ) (Fig. 4h) are neat codes of the junction phase dynamics (Devoret et al., 1985; Martinis et al., 1987). SCD is extracted by repeating the measurement several times (typically 10,000 events). All SCDs are measured at different temperatures as shown in the sketch reported in Fig. 4g. The width σ of each SCD is finally reported as a function of T in Fig. 4h. $T_{cr} = \hbar\omega_J/(2\pi k_B)$ indicates the crossover temperature from the thermal to the quantum regime (Devoret et al., 1985; Martinis et al., 1987). In the quantum regime σ does not depend on T (blue curve). To rule out the possibility that the saturation is due to noise or other spurious effects, the same measurements are realized in presence of an externally applied magnetic field (red curve). The magnetic field reduces I_c and thus ω_J , changing finally T_{cr} . The tuning of T_{cr} demonstrates that the saturation of σ is not due to extrinsic effects (Devoret et al., 1985; Martinis et al., 1987). A collection of experiments on the transition from TA to MQT is reviewed in (Massarotti and Tafuri, 2019b), including those on unconventional JJs. MQT and energy level quantization have been observed in YBCO biepitaxial GB JJs (Bauch et al., 2005; Bauch et al., 2006). The observation of MQT even for junctions with a lobe of the OP facing a node demonstrates that the quality factor Q of high critical temperature superconductor grain boundary JJs is however high enough to observe macroscopic quantum behaviors and that low energy quasi-particles in d-wave JJs are less harmful and dissipative than expected (Bauch et al., 2005; Bauch et al., 2006). In later studies (Longobardi et al., 2012), junction parameters have been finely tuned to explore phase dynamics in YBCO JJs in the moderately damped regime, where phase diffusion regime can also occur in an opportune range of temperatures. After the first escape process, the particle can be retrapped in one of the next wells and then released again, and this will be visible through distinctive features in SCDs measurements. This effect has been first clearly observed in low critical temperature superconductor JJs (Kivioja et al., 2005; Männik et al., 2005; Massarotti and Tafuri, 2019b).

Hamiltonian of a Josephson junction

The passage from the classical to the quantum description of a Josephson junction or of a superconducting electrical circuit is obtained by replacing classical variables with corresponding quantum operators. The Hamiltonian function is replaced by a function of operators. Operatively, the circuit Hamiltonian will be built by adding the kinetic energy associated with the charging energy of the capacitive elements $K = CV^2/2$ and the potential energy associated with the Josephson inductance $U_J = -E_J \cos \varphi$ and with the inductance of the superconducting leads $U_L = \Phi^2/(2L)$, where Φ is the magnetic flux (Devoret and Martinis, 2004; Wendin and Shumeiko, 2007; Wendin, 2017; Kockum and Nori, 2019; Kjaergaard et al., 2020). All these quantities have to be expressed in terms of φ for a given circuit element, which are connected to V and Φ by the Josephson Eq. (2) and by the relation $\Phi = \Phi_0 \varphi$ respectively. The commutation relation commonly reported in literature is $[\Phi, q] = 2i\hbar$ where Φ and q are conjugate operators (Likharev, 1986), or more simply $[\varphi, n] = i$, where n the induced charge on the capacitor measured in units of $2e$ (Cooper pairs). The charge n and phase φ operators do not commute, which means that their expectation values cannot be measured simultaneously. The circuit Hamiltonian is finally constructed by summing up the energies of all circuit elements: $H = \sum K(n_i) + U(\varphi_i)$ (Wendin and Shumeiko, 2007; Kjaergaard et al., 2020). If several circuit elements are connected in a closed loop, the flux quantization equation imposes a constraint on the phases of these elements: $\sum \varphi_i + \varphi_e = 2\pi n$, where $\varphi_e = 2e/\hbar \Phi_e$ and Φ_e is the phase associated with the applied magnetic flux.

The Hamiltonian of a current-biased Josephson junction will be therefore expressed as:

$$H = E_{co}n^2 - E_J \cos \varphi - \hbar I \varphi / (2e) \quad (7)$$

where $E_{co} = (2e)^2/(2C)$ is the charging energy and I is the applied current. Quantum Josephson junctions with either a well-defined charge or phase variable will depend on the relative magnitude of $E_c = E_{co}n^2$ and E_J (phase for $E_J \gg E_c$, charge for $E_J \ll E_c$ respectively) (Clarke and Wilhelm, 2008).

The Hamiltonian of the Josephson junction can be part of a more general Hamiltonian describing a generic circuit (Devoret and Martinis, 2004; Wendin and Shumeiko, 2007; Wendin, 2017; Kockum and Nori, 2019; Krantz et al., 2019; Kjaergaard et al., 2020). The Cooper pair box, which consists of a superconducting island connected to a superconducting reservoir through a small junction, has been the first superconducting qubit whose quantum state was manipulated coherently (Nakamura et al., 1999). Its Hamiltonian is:

$$H = E_{co}(n - n_g)^2 - E_J \cos \varphi \quad (8)$$

where $n_g = -C_g V_g/(2e)$ plays the role of external controlling parameter, and C_g is the gate capacitance. Similar expressions describe other quantum circuits, from phase to flux qubits, from the transmon and the quantronium to the fluxonium (Devoret and Martinis, 2004; Koch et al., 2007; Martinis, 2009; Wendin, 2017). Solving the Hamiltonian for each specific circuit will allow to find the energy-level structure of the system.

Temperature and magnetic dependence of the critical current and of I-V curves

Temperature dependence of I_c

The temperature dependence of I-V curves is a standard key reference to understand the nature of the junction. Accurate predictions exist to evaluate deviations of the $I_c R_n$ vs T dependence from the tunnel limit represented by the Ambegaokar-Baratoff (AB) regime valid for the SIS configuration (Ambegaokar and Baratoff, 1963). In point contacts in the dirty (KO1), where the mean free path l is

Fig. 5 (a) $I_c R_n(T)$ is reported in units normalized to the gap value Δ as a function of the temperature T , for different values of the ratio between the barrier length L and ξ_n . (b) In a S-F-S junction $I_c R_n$ is reported in units normalized to the critical temperature T_c as a function of T/T_c , for different values of the exchange field H . Above a critical field an additional minimum in $I_c R_n$ signals the $0-\pi$ transition. (c) $I_c R_n(T)$ is calculated for different misorientation angles in HTS d-wave GB JJs: curve a d_0/d_0 ; curve b $d_0/d_{\pi/8}$ and curve c $d_0/d_{\pi/4}$. (a) Adapted from Ref. Likharev KK (1979) Superconducting weak links. *Reviews of Modern Physics* **51**: 101; (b) Adapted from Ref. Golubov AA, Kupriyanov MY and Il'ichev E (2004) The current-phase relation in Josephson junctions. *Reviews of Modern Physics* **76**: 411; (c) Adapted from Ref. Tanaka Y and Kashiwaya S (1997) Theory of Josephson effects in anisotropic superconductors. *Physical Review B* **56**: 892

shorter than the length of the weak link L , ($l < L$) (Kulik and Omelyanchuk, 1975) and clean (KO2), where ($l > L$) (Kulik and Omelyanchuk, 1977) limits, the values of I_c at $T = 0$ K are higher than AB value. If a metallic barrier N replaces the insulator I , the $I_c R_n(T)$ is quite different and even changes concavity (Likharev, 1986). In Fig. 5a a variety of qualitatively different behaviors, including the transition from the short ($L < \xi_n$) to the long ($L > \xi_n$) regime, is reported (Likharev, 1979; Delin and Kleinsasser, 1996; Golubov et al., 2004). The tail in the exponential growth and the width of the intermediate region substantially depends on L/ξ_n (Barone and Paternò, 1982; Likharev, 1979; Golubov et al., 2004). Finer quantitative deviations depend on details of the proximity effect and on boundary conditions.

Radically different $I_c R_n(T)$ curves are measured, when a $0-\pi$ transition is induced by changing the temperature with a characteristic non-monotonous dependence of the $I_c R_n(T)$. This is visible in Fig. 5b when the exchange field H is increased above a certain threshold in a S-F-S junction (Ryazanov et al., 2001; Golubov et al., 2004; Buzdin, 2005). A peculiar $1/T$ scaling of the $I_c R_n$ has been predicted for ideal interfaces in HTS d-wave GB JJs (Barash et al., 1996; Tanaka and Kashiwaya, 1997; Riedel and Bagwell, 1998; Kashiwaya and Tanaka, 2000; Lofwander et al., 2001). This is due to the change in the dispersion relation for the ABSs, and the corresponding angle integrated current-phase relation, which is particularly relevant for high misorientation angles in GB JJs. In the resonant case, the splitting of the levels, and consequently the width of the Andreev band, will be particularly large, proportional to $D^{1/2}$. The (maximum) $I_c R_n$ is proportional to $D^{1/2}$, and is much larger than the AB value in conventional s-wave tunnel junctions, which is proportional to D (Likharev, 1979; Tanaka and Kashiwaya, 1997). This is shown in Fig. 5c, where $I_c R_n(T)$ is calculated for different misorientation angles in HTS d-wave GB JJs. Using the notation d_{01}/d_{02} , by increasing the misorientation angle from d_0/d_0 (curve a) to $d_0/d_{\pi/8}$ (curve b) and finally $d_0/d_{\pi/4}$ (curve c), dramatic changes occur in the shape of the $I_c R_n(T)$. In (c) $I_c R_n(T)$ does not saturate (Golubov et al., 2004).

Magnetic dependence of the critical current

The phase variation induced by an externally applied magnetic field has been since early times an invaluable and unambiguous tool to demonstrate the Josephson effect and a key fingerprint for plenty of sensor applications. This is widely documented in all textbooks and especially in (Barone and Paternò, 1982). Geometry of the junction, nature of the electrodes or of the barrier and their possible inhomogeneities determine specific space-dependent phase variations across the barrier, inducing Meissner screening magnetic interference effects, vortex formation and trapping, shielding and spontaneous supercurrents. All these effects cooperate to induce a distinctive spatial distribution of the critical current density across the junction barrier, and thus special features in the magnetic dependence of the I_c and of the $I-V$ curves.

The final expression of the dependence of the critical current on the external magnetic flux for an ideal rectangular geometry is:

$$I_s(\Phi) = I_s W L \left| \frac{\sin\left(\pi \frac{\Phi}{\Phi_0}\right)}{\pi \frac{\Phi}{\Phi_0}} \right| \quad (9)$$

In Eq. (10) the product $W \cdot L$ represents the junction magnetic area. The curve is reported in Fig. 6a.

Fig. 6 (a) Magnetic field dependence of the maximum Josephson current for ‘ideal’ JJ; (b) Dependence of the I_s on the magnetic field for a d-wave corner junction composed of Pb and YBCO electrodes, two symmetric maxima appear at finite magnetic fields. In (c) self-field effects induced by non-uniform distribution of the critical current occurring in long junctions, are visible in the magnetic pattern for ordinary junctions. The reduction and then the fading of the secondary lobes accompanied by a shift in the position of the minima of I_s also occurs in diffusive SNS junctions (d). In spin filter SFS JJs the I_s keeps memory of the history of how the magnetic field has been applied (e). The sequence of how the magnetic field is applied in the experiments is: red curve, black curve, blue curve. (b) Adapted from Wollman DA, Van Harlingen DJ, Giapintzakis J, Ginsberg DM (1995) Evidence for d-wave pairing from the magnetic field modulation of in $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ -Pb Josephson junctions. *Physical Review Letters* 74, 797–800; (c) adapted from Kirtley JR, Moler KA and Scalapino DJ (1997) Spontaneous flux and magnetic-interference patterns in $0-\pi$ Josephson junctions. *Physical Review B* 56: 886; (d) Adapted from Bergeret FS and Cuevas JC (2008) The vortex state and Josephson critical current of diffusive SNS junction. *Journal of Low Temperature Physics* 153: 304–324; (e) Adapted from Massarotti D, Pal A, Rotoli G, Longobardi L, Blamire MG and Tafuri F (2015) Macroscopic quantum tunnelling in spin filter ferromagnetic Josephson junctions. *Nature Communications* 6: 7376.

It can be derived the one-dimensional time-independent sine-Gordon equation combining Maxwell’s equation and the d.c. Josephson relation:

$$\frac{\partial^2 \varphi}{\partial x^2} = \frac{\sin \varphi}{\lambda_J^2} \quad (10)$$

where $\lambda_J = \sqrt{\Phi_0/(2\pi d\mu_0 J_c)}$ is the Josephson penetration depth and gives a measure of the distance from the edge where d.c. Josephson currents are confined, being $d = t + \lambda_R + \lambda_L$, with t the barrier thickness, $\lambda_{R(L)}$ the London penetration depth in the R(L) electrode and μ_0 the magnetic permeability of vacuum respectively.

We refer to textbooks and extensive reviews for a detailed account of theory and all deviations (Barone and Paternò, 1982; Kirtley, 2019a; Kirtley, 2019b). The magnetic patterns shown in Fig. 6 give finally a brief overview on some of the most significant deviations from the standard patterns. In all figures on y-axis I_c is always reported. On the x-axis depending on the origin of the curves (simulations or experiments) magnetic flux or magnetic field is reported, respectively. In a d-wave corner junction composed of Pb and YBCO electrodes, two symmetric maxima appear at finite magnetic fields (Fig. 6b) (Wollman et al., 1995). If the d-wave junction has more than the two facets of the corner junction, relative maxima in I_s appear between the two absolute maxima (for an applied magnetic flux $\Phi_{\max} = N\Phi_0/2$) (Smilde et al., 2002). The vanishing I_s at $\Phi = 0$ occurs for an even number of facets N . In Figs. 6c self-field effects induced by non-uniform distribution of I_s occurring in long junctions, are briefly sketched for ordinary junctions (Kirtley et al., 1997; Barone and Paternò, 1982). When increasing the width W of the junction with respect to the Josephson penetration depth λ_J , lobes at higher fields tend to be smeared out and the characteristic interferometric behavior is even lost when W is larger than $10 \lambda_J$.

The reduction and then the fading of the secondary lobes accompanied by a shift in the position of the minima of I_s also occurs in diffusive SNS junctions (see 6d) (Bergeret and Cuevas, 2008). For W comparable or smaller than $\xi_H = \sqrt{\Phi_0/H}$ the formation of a linear array of vortices is not favored and the field acts as a strong pair-breaking mechanism monotonically suppressing I_s . The monotonic suppression of I_c is also obtained while increasing L , even for fixed W to about ξ_H (Bergeret and Cuevas, 2008). The

presence of higher harmonics in the current-phase relation also affects the magnetic response (Goldobin et al., 2007; Kirtley, 2019a; Kirtley, 2019b). A distinctive feature is the appearance of oscillations of I_S with twice shorter period in H when increasing the intensity of the second harmonic. SFS JJs are expected to generate several anomalous magnetic behaviors due to the magnetic nature of the barrier itself (Ryazanov et al., 2001; Buzdin, 2005). I_S keeps memory of the history of how the magnetic field has been applied and the magnetic pattern is hysteretic (see Fig. 6e) (Senapati et al., 2011; Massarotti et al., 2015).

Hybrid junctions using almost bi-dimensional flakes are posing new questions also on the magnetic dependence of I_S . In addition to extrinsic features as those for instance induced by the way contacts are placed in a typical coplanar junction configuration, the intrinsic nature of the barrier may add special fingerprints. A recent example in a Ti/Al-InAs/GaSb-Ti/Al junction is given by the influence of edge states (Pribyl et al., 2015). Here gate-tuning between edge-dominated and bulk-dominated regimes of superconducting transport is demonstrated through superconducting quantum interference. The edge-dominated regime arises only under conditions of high-bulk resistivity, which has been associated with the two-dimensional topological phase. For wide barriers, supercurrents will flow along distant edges resembling the typical response of a SQUID (Pribyl et al., 2015).

Emerging trends: From qubits to hybrid JJs

The new frontiers of the Josephson effect are currently developing along a few exciting and challenging directions.

Low temperature Josephson junctions for qubits, quantum circuits and superconducting electronics

JJs are the fundamental cells for quantum bits and quantum circuits with a variety of functionalities.

Superconducting qubits encode information in the energy eigenstates of Josephson junction-based electronic circuits (Clarke and Wilhelm, 2008; McDermott, 2009; Martinis, 2009; Oliver and Welander, 2013; Devoret and Schoelkopf, 2013; Krantz et al., 2019; de Leon et al., 2021).

The first cornerstone was the experiment in 1999 where time-resolved coherent oscillations in a superconducting qubit were observed (Nakamura et al., 1999). Further key steps were the observation of coherent oscillations in coupled superconducting qubits (Pashkin et al., 2003; Yamamoto et al., 2003) and the significant improvements of the coherence times of these devices (Clarke and Wilhelm, 2008; Vion et al., 2002; Devoret and Schoelkopf, 2013; Krantz et al., 2019; Kjaergaard et al., 2020). There are currently several types of superconducting qubits with different circuit construction. The highly anharmonic Josephson potential allows to selectively excite the states used as basis of the qubit, and to avoid contributions from other energy levels. Thermal energy must be sufficiently low to avoid incoherent mixing of eigenstates ($k_B T < \omega_{01}$, where ω_{01} is energy quantum associated with the transition between the ground state $|0\rangle$ and the first excited state $|1\rangle$ of the qubit), and the macroscopic degree of freedom must be sufficiently decoupled from other degrees of freedom for the lifetime of the quantum states to be long on the characteristic time scale of the system. From the requirements $k_B T < \omega_{01}$ and $\omega_{01} < \Delta$ junctions need to be fabricated with materials with a $T_c > 1$ K. Aluminum JJs guarantee long coherence times T_1 (T_1 is the time required for a qubit to relax from $|1\rangle$ to $|0\rangle$) (Clarke and Wilhelm, 2008; Martinis, 2009). The transmon (Koch et al., 2007) and x-mon (Barends et al., 2013) consist of a capacitively shunted JJ where the junction acts as a nonlinear inductor. The fluxonium qubit (Manucharyan et al., 2009) is an inductively shunted JJ. By applying a magnetic flux through a superconducting loop, its potential well structure can be controllably modified. The capacitively shunted flux qubit (You et al., 2007; Steffen et al., 2010) is a SQUID loop with three JJs, shunted by a large capacitor where the qubit state is an energy eigenstate of the persistent current in the SQUID loop. The gatemon uses a voltage-tunable semiconductor weak-link barrier for the Josephson junction (Larsen et al., 2015). In all these devices, the JJs act as nonlinear elements, providing anharmonicity to the energy levels of the circuit. Most of these superconducting qubits were strongly coupled to photons stored in high-quality coplanar waveguide resonators, that would protect qubits from decoherence and promote techniques both for read out of their state and for their coupling in a quantum computer architecture (Blais et al., 2021; Blais et al., 2021). The first experimental realization of a circuit QED system achieving the strong-coupling regime of light-matter interaction was realized in 2004 (Chiorescu et al., 2004; Krantz et al., 2019; Wallraff et al., 2004).

Currently reference fidelity is on a single-qubit gate 99.97%, on readout 99.8%, and on two-qubit gate operations 99.5% (Jurcevic et al., 2021), respectively. T_1 times are typically about 100 μ s (Krantz et al., 2019; Kjaergaard et al., 2020). For fixed-frequency transmon qubits, the time interval within which information stored in a single qubit is lost, generally referred to as the coherence time T_2 , can be increased to about $\approx T_1 \approx 100$ μ s with opportune sequences of multiple pulses. Typical gate times are around a few hundred nanoseconds (Sheldon et al., 2016; Paik et al., 2016). Tunable transmons or capacitively shunted flux qubits can allow for much faster gate times, around tens of nanoseconds, but their tunability also renders them more susceptible to flux noise (Kjaergaard et al., 2020). Circuit QED is paving the way to the development of quantum-limited amplifiers (Clerk et al., 2010; Roy and Devoret, 2016; Siddiqi et al., 2004; Vijay et al., 2011) and single-microwave photon detectors (Besse et al., 2018; Kono et al., 2018; Lescanne et al., 2020). The generation and routing of control pulses involve a substantial experimental overhead in the form of room-temperature and cryogenic electronics hardware. An attractive candidate for the control of large-scale qubit arrays is the single flux quantum (SFQ) digital logic family (Opremcak et al., 2018). In SFQ digital logic, classical bits of information are encoded in fluxons (Mukhanov et al., 2019).

Both bulk materials and surface and interfaces induce decoherence affecting the final qubit performances. Progress in material science is fundamental to face issues related to substrate dielectric loss, excess quasiparticles in superconducting metal causing

dissipation and dephasing, the presence of uncontrolled oxides and contaminants at interfaces hosting two-level systems, surface spins and charges causing flux noise and charge noise, respectively. Better quality junction is an important issue to improve qubit performances (Clarke and Wilhelm, 2008; McDermott, 2009; Martinis, 2009; Oliver and Welander, 2013; Devoret and Schoelkopf, 2013; de Leon et al., 2021), also to contribute to overcome the main intrinsic limitation on the coherence of superconducting qubits resulting from low-frequency noise, notably $1/f$ noise. This arises from a uniform distribution of two-state defects. Each defect produces random telegraph noise, and a superposition of such uncorrelated processes leads to a $1/f$ power spectrum. Recognized sources of $1/f$ noise are (Clarke and Wilhelm, 2008): (1) critical-current fluctuations, which arise from fluctuations in the transparency of the junction caused by the trapping and untrapping of electrons in the tunnel barrier (van Harlingen et al., 2004); (2) charge fluctuations, which arise from the hopping of electrons between traps on the surface of the superconducting film or the surface of the substrate and this motion induces charges onto the surface of nearby superconductors; (3) magnetic-flux fluctuations. Despite the successful use of Al junctions, two-level defects (TLDs) in AlO_x tunnel barrier remain one of the major sources of decoherence in superconducting qubits (Martinis et al., 2003; McDermott, 2009; Oliver and Welander, 2013; Grabovskij et al., 2012).

Hybrid Josephson junctions uncovering emergent phenomena: from semiconducting and ferromagnetic barriers to topological insulators and Van der Waals crystals

Hybrid Josephson junctions are driving research in other relevant directions. Here “hybrid” stands for a barrier which, differently from a simple insulator or a normal metallic layer, can add novel functionalities to the Josephson coupling, transferring the specific features of the barrier to the coherent flow of the carriers such as topological states, ferroelectricity, magnetoelectricity, non-collinear magnetism and emergent properties from twisted heterostructures. Barriers leading to hybrid JJs are for instance ferromagnets, semiconductors, topological insulators (TI), graphene (G), nanotubes. Van der Waals (vdW) crystals can be superconducting and can work as electrodes and as barriers as well. Barriers for hybrid junctions are frequently two-dimensional (2D) sheets or nanowires. Some of the above-mentioned barriers are also commonly reported as “quantum materials”. The coplanar junction configuration is particularly convenient for hybrid junctions because it avoids the extremely challenging critical step of the barrier deposition on the superconducting film. The components can be obviously inverted when the superconductor has more critical conditions to be deposited as occurring for instance in HTS JJs. Nowadays, among the barriers listed above only ferromagnets are easily integrated into trilayers and not necessarily use coplanar layout.

The semiconducting barrier

In S-Sm-S systems, interface effects and boundary conditions will eventually tune the superconducting proximity effect and the capability of transferring coherence from the electrodes to the barrier (Barone and Paternò, 1982). An intuitive picture can be derived by standard proximity arguments by investigating the induced coherence length in the semiconducting barrier ξ_{sm} . ξ_{sm} depends on the carrier density through the diffusion constant and can be tuned, for instance, through a gate voltage for high transmittance S-Sm interface (Barone and Paternò, 1982; Kleinsasser and Jackson, 1990; Takayanagi et al., 1995; Tafuri, 2019). These barriers commonly are schematized as two-dimensional electron gas (2DEG) systems and their properties can be tuned through the gate from the weak localization to the strongly localized regime, thus tuning I_c and R_n values and I–V curves (Takayanagi et al., 1995). One of the ultimate targets for this type of device with Sm barrier has always been the challenging realization of a superconducting Josephson field-effect transistor (Jo-FET) (Mannhart, 1996).

Topological insulators

The fractional Josephson effect is known to be a characteristic phenomenon of topological Josephson junctions hosting Majorana zero modes (MZMs), where the Josephson current has a 4π (rather than a 2π) periodicity in the phase difference between the two topological superconductors (Kitaev, 2001; Fu and Kane, 2008; Mourik et al., 2012; Beenakker, 2015; Alicea, 2012). Topological phases of matter have attracted much attention in condensed matter physics. One of the characteristic features of topological phases of matter is the presence of symmetry-protected gapless boundary states that are robust against weak perturbations respecting relevant symmetry. The robustness is related to topology of wave functions and is important from the perspective of device applications as well as fundamental physics. Interesting ballistic and mesoscopic transport effects are also expected implementing materials with a Dirac dispersion such as TI and G. These phenomena can be investigated by tuning the electron concentration of the Dirac material at the Dirac point. Despite claims on the observation of signatures of Majorana fermions so far, a decisive and unambiguous evidence of the existence of MZMs is still missing (Sumita and Furusaki, 2021; Galaktionov and Zaikin, 2021). It is widely believed that superconducting junctions involving topological insulators and hosting Majorana-like bound states may exhibit an unusual “fractional” (4π -periodic) ac Josephson effect. The 4π -periodic CPR stays as a quite unusual and characteristic feature not occurring in a standard JJ. Inner properties of any weak link between two conventional superconductors may influence its critical current and the form of CPR but not its periodicity in ϕ , which is fundamentally determined by the periodicity of the charge space reciprocal to the phase one (Galaktionov and Zaikin, 2021; Sumita and Furusaki, 2021). In 4π -CPR, the charge transfer between superconducting condensates on both sides of the junction should be provided by quasiparticles with charge e rather than by Cooper pairs with charge $2e$.

Pronounced Shapiro steps at fractional frequencies have been detected in a number of microwave experiments performed with HgTe- and BiSb-based superconducting junctions (see for instance Wiedenmann et al., 2016 and references therein). Multiple

Andreev reflection (MAR) are also expected to play an important role in experiments with junctions involving topological insulators (Galaktionov and Zaikin, 2021). Electrodynamics of these junctions is poorly understood because of difficulties in modeling effective capacitance and dissipation of the junctions. Here heating effects may have more dramatic effects because of the lower dimensionality of the system. Within this framework, junctions of more than two superconducting terminals have gained renewed interest with the perspective of multiple supercurrents simultaneously transiting across the junction (de Bruyn Ouboter et al., 1995; Amin et al., 2002a; Amin et al., 2002b; van Heck et al., 2014; Riwar et al., 2016; Pankratova et al., 2020).

The ferromagnetic barrier

In a ferromagnetic JJ, exchange energy (E_{ex}) in magnets imposes a finite momentum to Cooper pairs, leading to a modulation of spatially damped oscillations of the OP when penetrating the ferromagnetic barrier over the decay length scale. Depending on the JJ barrier thickness, the ground state can either be a 0-junction with equal superconducting phases on both sides or a π -junction. Experiments have shown the presence of 0- π transitions by tuning the F-layer thickness in metallic or alloyed magnets. (Buzdin, 2005; Bergeret et al., 2005; Linder and Robinson, 2015; Eschrig, 2015). Magnetic insulator barriers in JJs are also fascinating for their spin filtering tunnel properties (Senapati et al., 2011); also in these junctions macroscopic quantum tunneling has been observed (Massarotti et al., 2015). A vdW ferromagnetic JJ has been recently obtained by inserting a few-layer ferromagnetic insulator $\text{Cr}_2\text{Ge}_2\text{Te}_6$ into two layers of the layered dichalcogenide 2H-NbSe_2 superconductor. With atomically flat and magnetically sharp interfaces, these type of functional nanodevices may potentially serve as critical components for superconducting quantum circuits or memories (Ai et al., 2021).

vdW crystals integration into JJs and Twisted HTS JJs

This last experiment falls in a series of recent studies, where 2D vdW crystals have been integrated into JJs. vdW heterostructures are a promising material platform for quantum devices. Cleaved from pure bulk crystals, the surfaces of these heterostructures are pristine and atomically flat. When assembled into stacks, the layers are held together by weak bonds that do not strain the crystals. Weak vdW bonding between neighboring atomic layers also offers a unique opportunity for engineering atomic interfaces with controlled twist angles (Ribeiro-Palau et al., 2018). Careful adjustment of the twist angle can create the spatial periodicity of a moiré superlattice (Yoo et al., 2019) with narrow electronic bands and topological structure (Carr et al., 2020). Realizations of such ‘twistronics’ host a plethora of emergent electronic states, at the twisted interface of various vdW materials. This technique has been extended also to HTS (Frank Zhao et al., 2021). Twisted interfaces between stacked van der Waals cuprate crystals enable tunable Josephson coupling between in-plane anisotropic superconducting order parameters between nodal superconducting order parameters (SOP) across a twisted vdW interface (Frank Zhao et al., 2021). Employing a novel cryogenic assembly technique, Josephson junctions with an atomically sharp twisted interface between $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ (BSCCO) crystals have been realized. In $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ (BSCCO), superconducting CuO_2 bilayers are Josephson-coupled through insulating $[\text{SrO-BiO}]$ bilayers, where the crystal can be mechanically cleaved into atomically flat crystals. J_c sensitively depends on the twist angle, reaching the maximum value comparable to that of the intrinsic junctions at small twisting angles and is suppressed by almost two orders of magnitude close to 45° twist angle. The J_c dependence on the twist angle is consistent with d-wave expectations, in agreement with what was observed on grain boundary YBCuO biepitaxial Josephson junctions (Lombardi et al., 2002). Twisted bilayers of high- T_c cuprate superconductors have renewed arguments on topological phases with spontaneously broken time reversal symmetry (T) for certain twist angles with the key outstanding challenge to identify unambiguous signatures of these topological phases in experiments (Tummuru et al., 2022). A detection of the π -periodic term is by itself not sufficient to identify the topological phase. These more controlled heterostructures may give the opportunity to investigate fundamental issues raised since early time on HTS JJs. Another study on twisted ultrathin $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ substantially confirms that experimental results are extremely sensitive to atomic details of the junction structures (Zhu et al., 2021; Li et al., 1999), that can cause artifacts even for these very sophisticated techniques (Zhu et al., 2021).

Conclusion

We have gone through the concepts and the phenomenology of the Josephson effect guided by the key feature of a dissipationless current driven by a phase difference of the macroscopic wavefunction between the two superconducting electrodes. To this unique capability of transferring quantum mechanics rules to macroscopic objects and circuits, a Josephson junction adds the ability of being a versatile component of all superconducting circuits providing a series of unique properties including the nonlinear behavior used in all current qubit architectures. Progress in materials science and nanotechnology has allowed to enlarge the ‘parameter space’ of operation for Josephson junctions to unprecedented values and control. The continuous progress in realizing high quality LTS-based JJs consolidates expectations for a series of challenging applications, including the realization of multi-qubit quantum processors. Unconventional junctions keep opening novel problems, confirming a series of predictions and promoting the study of novel physical processes. This impressive experimental progress is accompanied by a formidable capability of handling theoretical problems of significant complexity. Diversity in Josephson junctions opens breath-taking ‘horizons’, also because of its unique capability to transfer quantum to the macroscopic real. Much remains to do.

Abstract

Superconductivity is a fascinating subject, which remains at the forefront of research in condensed matter physics in the 21st century. In this Chapter I review several directions of the research over the last two decades, with emphasis on unconventional superconductivity of strongly correlated electrons.

Key points

- Unconventional superconductivity of strongly correlated electrons can emerge from nominally repulsive electron-electron interaction. A static screening of electron-electron repulsion often gives rise to attraction in non-s-wave spatial channels, like *d*-wave, where the gap function changes sign along the Fermi surface. A dynamical screening reduces the repulsion at smaller frequencies and may give rise to spatially uniform *s*-wave superconductivity, where the gap function has a non-trivial phase winding between small and large frequencies.

Introduction

Superconductivity (SC) is one of most remarkable aspects of quantum physics of interacting electrons. Discovered in 1911 by Kamerlingh Onnes and his team of technicians, it preoccupied the minds of the most prominent physicists of the 20th century and remains at the forefront of condensed-matter physics in the 21st century. Many ideas that emerged from the study of superconductivity were extended to other fields of physics, famously serving as paradigms to explain the generation of a Higgs mass generation of the electroweak *W* and *Z* gauge bosons in particle physics.

In simple words, superconductivity is the ability of fermions to carry electric current without dissipation. In quantum physics such phenomenon is associated with the appearance of a macroscopic condensate, i.e., a quantum state in which 10^{23} particles “hold together” at the lowest quantum level and do not allow individual members to get swiped away by impurities, interactions with boundaries, etc. Bosons are capable to do this because any number of them can occupy a single quantum level, and the appearance of a macroscopic condensate of bosons is a well-known phenomenon of Bose-Einstein condensation. Fermions, on the other hand, are “lone wolves”—by Pauli principle, only two of them (with opposite spins) can occupy a single quantum level, others are expelled. However, if fermions form bound pairs, quantum mechanics teaches us that each pair has spin $S = 0$ or 1 , i.e., it is a boson. Paired fermions then condense and behave as one monolithic object, i.e., if they are forced to move in one direction by an applied electric field, they will continue moving even after the field is turned off.

Bardeen, Cooper, and Schrieffer (BCS) attributed pair formation to attractive interaction between electrons and phonons. Electron-phonon mechanism of SC has been successfully applied to explain the pairing in a large variety of materials, from Hg and Al to MgB_2 with $T_c = 39\text{ K}$. The discovery of SC in the cuprates and, later, in iron-pnictides signaled the beginning of the new era of “high-temperature superconductivity.” The vast majority of researchers believe that superconductivity in these systems, as well in ruthenates, heavy-fermion, and organic materials, does not come from electron-phonon interaction, by one reason or the other. This leaves a nominally repulsive electron-electron interaction as a potential pairing glue. In this Chapter I review some basic aspects of superconductivity due to electron-electron interaction (Basov and Chubukov, 2011; Chubukov and Hirschfeld, 2015; Tremblay and Chubukov, 2017; Armitage et al., 2010), discuss recent applications to several classes of materials (Basov and Chubukov, 2011; Chubukov and Hirschfeld, 2015; Tremblay and Chubukov, 2017; Armitage et al., 2010; Lee et al., 2006; Keimer et al., 2015) and strong coupling effects, including the interplay with non-Fermi liquid behavior near a quantum-critical point (Abanov and Chubukov, 2020).

Superconductivity due to electron-electron interaction

A brief history

The study of the pairing due to nominally repulsive electron-electron interaction started in 1960th, when it was realized that the pairing problem decouples between different angular momenta l , and bound pairs develop even if the interaction has a single attractive partial component $U_{l_0} < 0$ with some l_0 . Quantum mechanics tells that partial components with large l come from large distances, where a screened Coulomb potential has the long range oscillatory tail $\cos(2k_F r + \varphi_0)/r^3$ in 3D, where k_F is the Fermi momentum, (these are called Friedel oscillations). Hence, in some ranges of r a screened Coulomb interaction gets over-screened and becomes negative, i.e., attractive.

A bold step in this analysis has been made by Kohn and Luttinger (KL) in 1965 (Kohn and Luttinger, 1965; Fay and Layzer, 1968; Baranov et al., 1992). They obtained U_l at large l by separating non-analytic $2k_F$ screening and regular screening from other momenta. They argued that the first contribution to U_l scales as $1/l^4$, while the second one behave at large l as e^{-l} , i.e., is much smaller. Neglecting these regular terms, KL found that U_l with large odd l are definitely attractive, hence any rotationally invariant system with repulsive Coulomb interaction is unstable against pairing.

The situation at smaller l is less definite as one no longer can separate the non-analytic $2k_F$ contribution to the irreducible pairing vertex and regular contributions from other momenta. In this situation, one can only do perturbation theory to second order in some bare $U(q)$. For momentum-independent (Hubbard) interaction $U(q) = U$, KL attraction survives down to $l = 1$, which by far is the largest attractive component.

Modern studies—Applications to lattice systems

For lattice systems, the situation is more complex because angular components with different l no longer decouple. There is a partial decoupling between different irreducible representations, however their number is finite, and within each representation there is an infinite number of pairing channels, which do not decouple in the analysis of the pairing (Maiti and Chubukov, 2014; Kiesel et al., 2012). Nevertheless, the very idea that the electron-electron interaction, relevant to the pairing, differs from a regularly screened electron-electron repulsion (e.g., the Hubbard interaction at strong screening) due to “ $2k_F$ ” renormalizations from low-energy fermions turned out to be rather fruitful and allowed one to understand in simple terms the gap symmetry in various superconductors. I illustrate this on three examples below.

Fe-pnictides

Fe-pnictides are binary compounds of pnictogens, which are the elements from the 5th group: N, P, As, Sb, Bi. Superconductivity in these materials has been discovered in 2008 by Hosono and his collaborators. Later, superconductivity has been found also in Fe-chalcogenides—Fe-based compounds with elements from the 16th group: S, Se, Te. The family of Fe-based superconductors (FeSCs) includes 1111 systems $RFeAsO$ (R = rare earth element), 122 systems like XFe_2As_2 ($B = Ba, Na, K$) and AFe_2Se_2 ($A = K, Rb, Cs$), 111 systems like $LiFeAs$, and 11 systems, like $FeSe$. Parent compounds of most of FeSCs are metallic antiferromagnets. Because electrons, which carry magnetic moments, can travel relatively freely from site to site, antiferromagnetic order is often termed as a “spin-density-wave” (SDW), by analogy with, e.g., magnetism in Cr , rather than “Heisenberg antiferromagnetism”—the latter term is reserved for systems in which electrons are “nailed down” to particular lattice sites by very strong Coulomb repulsion. In some parts of the phase diagram a lattice rotational symmetry is spontaneously broken. Such a state is called a nematic. Superconductivity emerges upon either hole or electron doping (see Fig. 1), but can also be induced by pressure or by isovalent replacement of one pnictide element by another, e.g., As by P. In some systems, like $LiFeAs$ and $FeSe$, superconductivity emerges already at zero doping, instead of a magnetic order, but in $FeSe$ it is preceded by a nematic order (Basov and Chubukov, 2011; Chubukov and Hirschfeld, 2015; Tremblay and Chubukov, 2017; Armitage et al., 2010).

The electronic structure of FeSCs is fairly complex, with multiple Fermi surfaces (FS's), as evidenced by ARPES and quantum oscillations measurements. In most systems, there are two or three near-cylindrical hole FS's, centered at $k_x = k_y = 0$, and two electron FS's centered at (π, π) . For electron pockets, states inside the pockets are occupied, for hole pockets, states inside the pockets are empty.

Fig. 1 Schematic phase diagram of Fe-based pnictides upon hole or electron doping. In the shaded region, superconductivity and antiferromagnetism co-exist. Not all details/phases are shown. Superconductivity can be initiated not only by doping but also by pressure and/or isovalent replacement of one pnictide element by another. From Basov D.N., Chubukov A.V. (2011) *Nature Physics* 7: 273.

For proof-of-concept we consider a simpler problem: a 2D two-pocket model with one hole and one electron FS, both circular and of equal size (see Fig. 2 left). The free-fermion Hamiltonian is the sum of kinetic energies of holes and electrons:

$$H_2 = \sum_{k,\sigma} \varepsilon_c c_{k,\sigma}^\dagger c_{k,\sigma} + \varepsilon_f f_{k,\sigma}^\dagger f_{k,\sigma} \quad (1)$$

where c stands for holes, f stands for electrons, and $\varepsilon_{c,f}$ stand for their respective dispersions with the property the $\varepsilon_c(k) = -\varepsilon_f(k + Q)$, where Q is the momentum vector which connects the centra of the two FS's.

The two interactions that contribute to the pairing are intra-pocket density-density interaction G_4 and pair hopping G_3 , in which two fermions from one pocket transform into two fermions from the other pocket:

$$H_{\text{int}} = \sum_{[k, \sigma]} \frac{G_3}{2} \left(c_{k1,\sigma1}^\dagger c_{k2,\sigma2}^\dagger f_{k3,\sigma2} f_{k4,\sigma1} + \text{h.c.} \right) + \sum_{[k, \sigma]} \left(\frac{G_4}{2} c_{k1,\sigma1}^\dagger c_{k2,\sigma2}^\dagger c_{k3,\sigma2} c_{k4,\sigma1} + c \leftrightarrow f \right) \quad (2)$$

where $\sum_{[k, \sigma]}$ is short for the sum over the spins and the sum over all the momenta constrained to $k_1 + k_2 = k_3 + k_4$ modulo a reciprocal lattice vector. Both interactions are positive, i.e., repulsive, but they include all renormalizations from particle-hole channel, including “ $2k_F$ ” renormalizations. These interactions are often called *irreducible* particle-particle vertices to emphasize that they are considered “bare” interactions for particle-particle channel, but at the same time incorporate all renormalizations from the particle-hole channel (Maiti and Chubukov, 2014; Kiesel et al., 2012).

To analyze the pairing, one has to consider vertex functions for fermions on the FS for zero total incoming momentum (i.e., for fermions with momenta k and $-k$) and finite frequency Ω . If a pairing instability develops at some $T_c > 0$, then at $T = 0$ the fully renormalized vertex function has a pole in the upper half-plane of complex Ω , implying that perturbations above the normal state grow exponentially with time.

Because there are two pockets, there are three relevant vertices: $\Gamma_{hh}(\mathbf{k}_F, -\mathbf{k}_F; \mathbf{p}_F, -\mathbf{p}_F) = \Gamma_{ee}(\mathbf{k}_F, -\mathbf{k}_F; \mathbf{p}_F, -\mathbf{p}_F)$, where $\mathbf{k}_F$ and $\mathbf{p}_F$ belong to the same pocket, and $\Gamma_{he}(\mathbf{k}_F, -\mathbf{k}_F; \mathbf{p}_F, -\mathbf{p}_F)$, where $\mathbf{k}_F$ and $\mathbf{p}_F$ belong to different pockets. The renormalizations of irreducible $\Gamma_{hh} = \Gamma_{ee}$ and Γ_{he} come from the particle-particle-channel, like in BCS theory. The result is

$$\Gamma_{hh}^{\text{full}} = -\frac{1}{2} \left(\frac{G_4 + G_3}{1 + (G_4 + G_3)\Pi_{pp}} + \frac{G_4 - G_3}{1 + (G_4 - G_3)\Pi_{pp}} \right) \quad (3)$$

$$\Gamma_{he}^{\text{full}} = -\frac{1}{2} \left(\frac{G_4 + G_3}{1 + (G_4 + G_3)\Pi_{pp}} - \frac{G_4 - G_3}{1 + (G_4 - G_3)\Pi_{pp}} \right),$$

where $\Pi_{pp} = \Pi_{pp}(\Omega) = N_0(\log|\omega_c/\Omega| + i\pi/2)$, where N_0 is the density of states at the FS.

Fig. 2 FS topologies for a 2-pocket model for FeSCs (left), for hole-overdoped cuprate (center) and doped graphene (right). In pnictides there are hole and electron FS's (blue and orange circles, respectively). For cuprates and graphene one can have disconnected pieces or a singly-connected FS's, depending on the doping. The doping at which an open FS transforms into a closed one is called the Van-Hove doping. At this doping the density of states is logarithmically singular near the saddle points, marked by gray patches. From Maiti S., Chubukov A.V. (2014) In: Bennemann, Ketterson (eds.) *"Novel Superfluids"*, Chapter 15. Oxford Press.

The pole in Γ^{full} is in the upper half-plane when $G_4 - G_3$ is negative. How to get it? It is customary to model regular screening by replacing the Coulomb $U(r)$ by Hubbard U . If we do this, we get $G_3 = G_4 = U$, hence no instability. Let's now include $2k_F''$ renormalizations. They come from intra-pocket density-density and exchange interactions. The result is

$$\begin{aligned} G_3 &= U(1 + 2U\Pi_{ph}(Q)), \\ G_4 &= U(1 + 2U\Pi_{ph}(0)), \end{aligned} \quad (4)$$

where $\Pi_{ph}(q)$ is a particle-hole bubble at momentum Q . The condition $G_3 > G_4$ then reduces to $\Pi_{ph}(Q) > \Pi_{ph}(0)$. For fermions with one circular FS, $\Pi_{ph}(q)$ either stays constant or decreases with q , then this condition is not satisfied. However, in our case, there are two FS's, separated by Q , one of hole type and the other of electron type. One can easily verify that, in this situation, $\Pi_{ph}(Q)$ is logarithmically enhanced comparable to $\Pi_{ph}(0)$, hence irreducible G_3 is necessary larger than irreducible G_4 . This is lattice analog of KL scenario.

What kind of the pairing state we get? Both Γ_{hh}^{full} and Γ_{he}^{full} do not depend on the direction along each of the two pockets, hence the pairing state is necessary s -wave.

At the same time, near the pole $\Gamma_{hh}^{full} = -\Gamma_{he}^{full}$, which implies that the two-fermion pair wave function changes sign between hole and electron pockets. Such an s -wave state is often call s^{+-} .

The majority of researchers believe that s_{+-} is the correct gap symmetry for FeSCs. It is consistent with STM and neutron scattering data. Nevertheless, a conventional s -wave gap due to phonons and a d -wave gap symmetry for strongly hole doped 111 materials have also been proposed.

Cuprates

Cuprates are layered materials with one or more crystal planes consisting of Cu and O atoms (two O per Cu), and charge reservoirs between them. Superconductivity is widely believed to originate from electron-electron interactions in these CuO_2 planes. The undoped parent compounds are Mott insulators/Heisenberg antiferromagnets due to very strong Coulomb repulsion which prevents electron hopping from Cu to Cu and therefore localizes electrons near lattice sites (Lee et al., 2006; Keimer et al., 2015). Doping these insulating CuO_2 layers with carriers (by adding/removing electrons from/to charge reservoir) leads to a (bad) metallic behavior and to the appearance of high-temperature superconductivity. A schematic phase diagram of doped cuprates is shown in Fig. 3.

Fig. 3 The phase diagram for the cuprates. In similarity with FeSCs, parent compounds are antiferromagnets. Among differences, the most important one is that antiferromagnetism is of Heisenberg type, and is a part of Mott behavior. In the region below T^* , the system displays pseudogap behavior. d -wave symmetry of superconducting state holds for both hole and electron dopings. From Armitage N.P., Fournier P., Greene R.L. (2010) *Reviews of Modern Physics* 82: 2421.

There are several features in the phase diagram, like the pseudogap in hole-doped cuprates, which are still not fully understood, although a substantial progress has been made over the last few years (Basov and Chubukov, 2011; Chubukov and Hirschfeld, 2015; Tremblay and Chubukov, 2017; Armitage et al., 2010; Lee et al., 2006; Keimer et al., 2015).

By all accounts, the symmetry of the superconducting state does not change between small doping, where pseudogap physics is relevant, and doping above the optimal one. For these larger dopings, ARPES and quantum oscillation experiments show a large FS, consistent with Luttinger count for fermionic states. In this doping range, it is natural to expect that the pairing symmetry can be at least qualitatively understood by performing the same analysis as for Fe-based systems.

The FS for hole-doped cuprates is an open electron FS shown in Fig. 2 (center). The fermionic density of states is the largest near the points $(0, \pm\pi)$ and $(\pm\pi, 0)$, where two FS lines come close to each other (the density of states is logarithmically enhanced and actually diverges when the two FS lines merge at $(0, \pm\pi)$ and $(\pm\pi, 0)$ —this is termed as Van Hove singularity). The FS regions with the largest DOS mostly contribute to superconductivity, and, to first approximation, one can consider the FS in Fig. 2 (center) as consisting of four patches. Experiments clearly indicate that bound fermionic pairs are spin singlets. A spin-singlet pair wave function is an even function of momentum. This leaves two non-equivalent patches, which for definiteness we choose to be near $(0, \pi)$ and $(\pi, 0)$.

The resulting two-patch model is in many respects similar to the two-pocket model for Fe-pnictides, only instead of hole-hole, electron-electron, and hole-electron interaction we now have intra-patch and inter-patch interactions for two patches, which we label as 1 and 2. Introducing as before inter-patch repulsion G_4 and inter-patch pair-hopping interaction G_3 , we obtain, in full analogy with (3),

$$\begin{aligned} \Gamma_{11}^{full} &= -\frac{1}{2} \left(\frac{G_4 + G_3}{1 + (G_4 + G_3)\Pi_{pp}} + \frac{G_4 - G_3}{1 + (G_4 - G_3)\Pi_{pp}} \right) \\ \Gamma_{12}^{full} &= -\frac{1}{2} \left(\frac{G_4 + G_3}{1 + (G_4 + G_3)\Pi_{pp}} - \frac{G_4 - G_3}{1 + (G_4 - G_3)\Pi_{pp}} \right), \end{aligned} \quad (5)$$

and

$$G_3 - G_4 = 2U^2 (\Pi_{ph}(Q) - \Pi_{ph}(0)) \quad (6)$$

The two particle-hole polarization bubbles can be straightforwardly calculated for the lattice model of fermionic dispersion with hopping t (t^0) between nearest (next-nearest) neighbors. The result is that $\Pi_{ph}(Q) > \Pi_{ph}(0)$, hence irreducible G_3 again exceeds irreducible G_4 , and superconductivity develops. Near the pole, $\Gamma_{11}^{full} \approx -\Gamma_{12}^{full}$.

Now, in the two-pocket model for FeSCs, the sign changing pair wave-function changes sign between different FS pockets, but preserves the same sign along a given pocket. In two-patch model for the cuprates, the sign-changing wave function changes sign between the two ends of the same “arc” of the FS, i.e., it changes sign under $\pi/2$ rotation from x to y axis and necessarily passes through zero in between. The prototype wave function for such a state is $\cos k_x - \cos k_y$. According to a standard classification scheme, such a wave function belongs to B_{1g} representation and is often called d -wave because it changes sign 4 times along the full FS.

The d -wave symmetry of superconducting order parameter (often called gap function) in the cuprates has been firmly established by a number of experiments. In 2011, Juan Carlos Campuzano from Argonne National Laboratory, P. Johnson from Brookhaven National Laboratory, and Z.X. Shen from Stanford University were awarded the prestigious Oliver E. Buckley Condensed Matter Prize by the American Physical Society for innovative ARPES experiments, which established d -wave gap symmetry.

Doped graphene

The same logics can be applied to a system of fermions of a hexagonal lattice, at a so-called van Hove doping, when the system is about to undergo a topological transition between a singly connected large FS and a set of disconnected small FS's (Gonzalez, 2008; Nandkishore et al., 2012). Such a situation holds in a single-layer graphene at a doping when six separate Fermi pockets that emerge out of Dirac points, merge (Fig. 4). A van Hove doping of a single layer graphene has been achieved by placing *Ca* and *K* dopants above and below a graphene layer.

Near van Hove instability, low-energy physics is again described by a patch model, but now there are three non-equivalent patches, labeled 1, 2 and 3 in Fig. 2 (right). We introduce intra-patch and inter-patch vertices Γ_{ij} , $i, j \in (1, 2, 3)$ with $\Gamma_{ij} = \Gamma_{ji}$. Because the three patches are fully symmetric, the number of independent vertices is just two:

$$\begin{aligned}\Gamma_{11} &= \Gamma_{22} = \Gamma_{33} \\ \Gamma_{12} &= \Gamma_{13} = \Gamma_{23},\end{aligned}\quad (7)$$

and there are two irreducible pairing interactions, which like before we call G_3 and G_4 . Summing up ladder diagrams in the particle-particle channel, one obtains the result similar, but not identical to (5):

$$\begin{aligned}\Gamma_{11}^{full} &= -\frac{1}{3} \left(\frac{G_4 + 2G_3}{1 + (G_4 + 2G_3)\Pi_{pp}} + 2 \frac{G_4 - G_3}{1 + (G_4 - G_3)\Pi_{pp}} \right) \\ \Gamma_{12}^{full} &= -\frac{1}{3} \left(\frac{G_4 + 2G_3}{1 + (G_4 + 2G_3)\Pi_{pp}} - \frac{G_4 - G_3}{1 + (G_4 - G_3)\Pi_{pp}} \right).\end{aligned}\quad (8)$$

For Hubbard interaction the bare $G_3^0 = G_4^0 = U$ are again equal, i.e., at this level there is no superconductivity, but irreducible interactions are

$$G_4 = U(1 + 3U\Pi_{ph}(0)), G_3 = U(1 + 2U\Pi_{ph}(Q)) \quad (9)$$

where now Q is the momenta between van Hove points. Superconductivity develops when $\Pi_{ph}(Q) > (3/2)\Pi_{ph}(0)$. Computations of the polarization bubble shows that $\Pi_{ph}(Q)$ is again logarithmically singular and well exceeds $\Pi_{ph}(0)$. Then superconductivity does develop.

What is the symmetry of a pair wave function? Near the instability the ratio of inter-patch Γ_{ij}^{full} and intrapatch Γ_{ii}^{full} is $-1/2$, $= -\frac{D}{2}$ for $i \neq j$. If we view Γ_{ii}^{full} as the modulus square of the superconducting order parameter $|\Delta_i|^2$ and Γ_{ij}^{full} as $Re[\Delta_i \Delta_j^*]$, we find that the phase of complex Δ must change by $\pm \frac{2\pi}{3}$ between each pair of patches ($\cos \frac{2\pi}{3} = -\frac{1}{2}$). In other words, if the order parameter in patch 1 is Δ_1 , then $\Delta_2 = \Delta_1 e^{\pm 2\pi i/3}$ and $\Delta_3 = \Delta_1 e^{\pm 4\pi i/3}$. The two resulting structures of Δ are shown in Fig. 5. Each of the two candidate order parameters has *d*-wave symmetry, because if we extend it to the whole FS, we find that it changes sign 4 times.

Chiral superconductivity

The two order parameters in Fig. 5 represent counter clockwise and clockwise phase winding by 4π along the full FS. These order parameters are completely equivalent, i.e., there is an additional Z_2 symmetry of a superconducting wave function, which is different from a conventional $U(1)$ phase symmetry. The analysis of the Landau functional in the superconducting state shows that Z_2 symmetry gets broken, i.e., the system spontaneously chooses counter clockwise or clockwise phase winding. Such a state is called *d + id* or *d - id*. It breaks time reversal and inversion symmetries and is called a chiral superconductor. The nontrivial topology of the *d ± id* state manifests itself in exceptionally rich phenomenology, including a quantized spin and thermal Hall conductance, and a quantized boundary current in magnetic field (Gonzalez, 2008; Nandkishore et al., 2012). Theoretical analysis of such

Fig. 4 Schematic phase diagram of doped graphene. T_c is the instability temperature toward spin singlet *d + id* or spin triplet *f*-wave SC states, or SDW state. T_c is plotted against doping (n). Doped Graphene is expected to be mostly superconducting with competition with the SDW phase near the Van-Hove region. Modified from Kiesel M.L., et al. (2012) *Physical Review B* 86: 020507(R).

Fig. 5 The phases of the pair-wave functions at the patches (regions with enhanced density of states). The left and right represent the two Z_2 breaking d -wave solutions $d + id$ or $d - id$. From Maiti S., Chubukov A.V. (2014) In: Bennemann, Ketterson (eds.) “*Novel Superfluids*”, Chapter 15. Oxford Press.

superconductors and a search for their practical realizations are integral parts of modern studies of superconductivity. The most frequently discussed example is spin-triplet $p + ip$ superconductivity, which has multiple applications for quantum computation (Sato and Ando, 2017). In practical applications, $p + ip$ gap symmetry has been discussed in the context of superfluidity in ^3He . It was proposed for Sr_2RuO_4 , but recent experiments cast doubt on this explanation. Understanding of the pairing symmetry in Sr_2RuO_4 , which by all accounts, falls into a weak coupling category, is another actively explored area of modern research on superconductivity.

Twisted bilayer graphene

Superconductivity with highest $T_c \sim 3\text{ K}$ and strongly correlated behavior around it have been recently discovered in a twisted bilayer graphene (TBG), consisting of two graphene sheets rotated by a “magic” angle (Cao et al., 2018; Stepanov et al., 2020) (Fig. 6). STM data for TBG show sharp van Hove peaks, and several researchers argued that superconductivity in TBG emerges by the same reason as in a single graphene sheet, and has a chiral d -wave symmetry. Others, however, argued that superconductivity may come from electron-phonon interaction and is likely s -wave. Another proposal is that superconductivity is ultimately a fundamentally novel phenomenon, related to insulating states nearby (Khalaf et al., 2021). Another potential novel feature of superconductivity in TBG is suggested breaking of lattice-rotational symmetry below T_c , in which case the ordered state becomes a nematic superconductor. Theoretical understanding of nematic superconductivity here and in other systems is another rapidly developing field of research, along with the studies of partially melted superconducting states, in which fluctuating Cooper pairs do not establish phase coherence, but already break Z_2 time-reversal symmetry or symmetry associated with a rotational invariance.

s -wave superconductivity from repulsion

Another issue, first discussed in early studies of superconductivity, but revisited recently in the context of superconductivity in strontium titanate and related systems, is whether one can potentially get an ordinary s -wave superconductivity with momentum-independent order parameter from repulsion. This question has been raised for electron-phonon superconductivity

Fig. 6 The phase diagram of TBG. Reproduced from Cao Y., et al. (2018) *Nature* 556: 43; Stepanov P., et al. (2020) *Nature* 583: 375, with permission from Springer Nature.

as Coulomb repulsion is present in systems, which are believed to be *s*-wave electron-phonon superconductors, and is larger than electron-phonon attraction. A frequently cited explanation is that in cases where the Fermi energy E_F is much larger than the Debye frequency ω_D , there is a wide range of frequencies where the repulsive Coulomb repulsion is logarithmically renormalized down by ladder series in the same particle-particle channel that would give rise to pairing in case of attraction (the Tyablikov-McMillan logarithm). If this range is wide enough, the renormalized Coulomb repulsion becomes smaller than the electron-phonon attraction at energies below ω_D .

Upon closer examination, this explanation appears incomplete as Tyablikov-McMillan renormalization holds for the full interaction, i.e., for the sum of electron-electron and electron-phonon interactions. Under the renormalization this full interaction decreases, but does not change sign, i.e., remains repulsive. How one can get superconductivity in this situation?

It has been originally discussed quite some time ago for large E_F/ω_D and has been re-analyzed recently in the context of superconductivity in systems with small Fermi energy, like SrTiO_3 , $\text{Pb}_{1-x}\text{Tl}_x\text{Te}$, half-Heusler compounds, where E_F and ω_D are comparable and Tyablikov-McMillan reasoning does not work.

It has been realized that the actual reason why electron-phonon superconductivity holds despite larger Coulomb interaction, is that the full interaction on the Matsubara axis (where it is real) is a dynamical one, $V(\Omega_m)$, and although a phonon-mediated attraction does not invert the sign of $V(\Omega_m)$, it nevertheless reduces it at frequencies below the Debye energy. A convenient way to model $V(\Omega_m)$ is to treat it as a sum of two parts: a constant Hubbard repulsion U , and a frequency-dependent attractive part due to electron-phonon interaction:

$$V(\Omega_m) \propto U - \frac{U_{el-ph}}{1 + (\Omega_m/\Omega_1)^2}, \quad (10)$$

where Ω_1 is of order of the Debye energy and Ω_m is a bosonic Matsubara frequency. A similar model has been recently used for dynamically screened electron-electron interaction in single-crystal Bi, where Ω_1 is of the order of plasma frequency.

For $U > U_{el-ph}$, $V(\Omega_m) > 0$ for all frequencies. Yet, because the interaction is dynamical, one can, to first approximation, replace it by a step-like function, with different values at small at large frequencies (regions 1 and 2) and solve a set of coupled equations for Γ_{11} , Γ_{22} , and Γ_{12} . The set is qualitatively the same as in (3), (5), (8), and the analogs of G_3 and G_4 are approximately U and $U - U_{el-ph}$. Without electron-phonon attraction, $G_3 = G_4 = U$. Once electron-phonon attraction is added, G_3 becomes larger than G_4 , and superconductivity develops. Like in previous cases, this order parameter necessarily changes sign, but here it does this as a function of frequency, i.e., the signs of the gap function at small and large ω_m are different. The McMillan formula $T_c \sim \Omega_1 e^{-1/(N_F U - \lambda^*)}$, where $\lambda^* \sim 1/\log E_F/\Omega_1$ is reproduced for $E_F \gg \Omega_1$ once one integrate out fermions with high-frequencies and obtain an effective interaction between low-energy fermions. This interaction is attractive when $N_F U > \lambda^*$, but it incorporates the fact that the sign of the order parameter at large frequencies is opposite to that at small frequencies.

Superconductivity at strong coupling

The weak coupling approach, based on second-order renormalization of the Hubbard interaction, is highly useful for the understanding of the symmetry of the superconducting order parameter for a particular material, but at the same time is incomplete as it is based on the assumptions that the bare interaction in the relevant pairing channel is zero, and that fermions are weakly interacting quasiparticles. These assumptions work for the case of a weak Hubbard interaction, but not beyond it. Indeed, a generic screened Coulomb interaction is larger at small momentum transfer, hence, in the notations used above, a bare G_4 is larger than a bare G_3 . To get an attraction, the “ $2k_F$ ” screening must overcome this difference, and to verify this one necessary has to go beyond weak coupling.

Modern studies of superconductivity beyond weak coupling can be broadly divided into three classes: (i) The analysis of “ $2k_F$ ” screening beyond second order in perturbation, but still at weak coupling. This is most often done using some version of renormalization group (RG) analysis; (ii) The analysis of the pairing in a metal, mediated by a soft collective boson in either spin or charge channel. The most studied examples here are pairing by spin fluctuations and by Ising-nematic fluctuations. This is valid for an intermediate coupling strength, when on one hand interaction is strong enough to bring the system close to an instability in spin or charge channel, and on the other the carriers retain their itinerant character; (iii) The analysis of the pairing in the truly strong coupling regime, when interaction is strong enough to localize most of the carriers. The most studied example here is pairing of a doped Mott insulator, extensively discussed for the cuprates, and pairing of a doped Chern insulator, recently suggested in the studies of TBG.

Renormalization group analysis

The RG approach is an attempt to go beyond the lowest order in perturbation already for weak coupling, when dimensionless $g_3 = N_F G_3$ and $g_4 = N_F G_4$ are small. A good starting point here is the BCS approach, in which one assumes that the bare dimensionless pairing interaction g^0 is small and neglects all regular corrections in powers of g^0 , but sums up series of corrections in $g^0 L$, where $L = \log W/T$ is a Cooper logarithm. Within BCS approximation, the series in $g^0 L$ are geometrical, and the dressed $g = g^0/(1 - g^0 L)$ (The dressed vertex $\Gamma = \Gamma^0(g/g^0) \propto (1 - gL)$). The flow of the dressed g with running L (i.e., with changing

temperature) can be cast into the differential equation $\dot{g} = g^2$, where $g^* = dg/dL$ and BCS result about the pairing instability at weak coupling can be reformulated as the divergence of the running g as the temperature approaches T_c (or, equivalently, as the divergence of the running vertex Γ).

This reasoning has been extended in the last two decade to extend the analysis of the irreducible vertex beyond second order in perturbation. In all three cases discussed in Sec. III the particle-hole polarization $\Pi_{ph}(Q)$ is logarithmically enhanced by one reason or the other. The idea is then to treat logarithmic terms in the particle-hole channel on equal footing with logarithmic renormalizations in the particle-particle channel and detect the flow of irreducible g_3 and g_4 simultaneously with their renormalizations in the particle-particle channel. As long as g_i are small and $g_i L \leq 1$, this can be done rigorously. The corresponding RG procedure is called it parquet RG as logarithmic renormalizations are extended simultaneously into two particle-hole and particle-particle channels, which can be viewed as the two “perpendicular” directions. A similar but somewhat more involved *functional* RG has also be applied for this purpose. There are two goals of parquet/functional RG analysis. First to verify whether in the flow the running g_3 becomes larger than g_4 , even if bare g_4 was larger. If so, then the system self-generates attraction below some upper cutoff, determined by the system. Second, to understand the interplay between superconductivity and particle-hole orders, which can also develop under RG flow.

As an illustration, consider the 2-pocket model for FeSCs. For the RG analysis, we need to add two other interactions between low-energy fermions: interaction between fermionic densities in the two pockets, g_1 , and intra-pocket density-density interaction g_2 ($c_{\alpha}c_{\alpha}f_{\beta}f_{\beta}$ and $c_{\alpha}f_{\alpha}f_{\beta}c_{\beta}$ terms, respectively). At second order, these two interaction renormalize the irreducible g_3 and g_4 . Beyond second order, they also flow with L and can give rise to SDW, charge-density-wave (CDW), nematic and other orders. The full set of parquet RG equations is

$$\begin{aligned}\dot{g}_1 &= g_1^2 + g_3^2 \\ \dot{g}_2 &= 2g_2(g_1 - g_2) \\ \dot{g}_3 &= 2g_3(2g_1 - g_2 - g_4) \\ \dot{g}_4 &= -g_3^2 - g_4^2.\end{aligned}$$

The solution is shown in Fig. 7. We see that g_3 does become larger than g_4 above some L , even if its bare value was smaller. The competition between superconductivity and other orders is determined by the behavior of different g_i near the fixed trajectory, where all $g_i \propto 1/(L_{cr} - L)$ and $L_{cr} = \log W/T_{cr}$, where T_{cr} is the highest instability temperature.

Pairing by spin and charge fluctuations

When g_i are not small, neglecting regular corrections in g_i is not an option. Because no controlled calculations are possible in this case (except for specific extensions to, e.g., large number of fermionic flavors) one frequently discussed option is to adopt a semi-phenomenological approach based on the experimental phase diagram. Many materials, in which superconductivity is believed to be of electronic origin, the phase diagram shows some other ordered phases close to where superconductivity exists: undoped cuprates display antiferromagnetic order, parent compounds of FeSCs show either SDW or nematic order, in doped graphene there are strong SDW and CDW correlations, etc. In this situation, it is tempting to consider the propagator of a soft boson in either spin or charge channel as a pairing glue for superconductivity, i.e., consider pairing mediated by spin or charge fluctuations.

Fig. 7 The flow of dimensionless couplings $g_{1,2,3,4}$. g_3 grows and eventually crosses g_4 , which becomes negative at a large enough RG scale. From Maiti S., Chubukov A.V. (2014) In: Bennemann, Ketterson (eds.) “*Novel Superfluids*”, Chapter 15. Oxford Press.

From theory viewpoint, in this approach one extends the computation of the irreducible vertex functions in the particle-particle channel by restricting to a particular set of diagrams beyond second order. The vertex function can be generally split into spin and charge components: $\Gamma_{\alpha\beta\gamma\delta} = \Gamma_c \delta_{\alpha\gamma} \delta_{\beta\delta} + \Gamma_s \sigma_{\alpha\gamma} \sigma_{\beta\delta}$, here σ_i are Pauli matrices. A re-examination of second order results in Sec. III shows that for a repulsive interaction, the “ $2k_F$ ” screening enhances the spin component of the interaction at momentum $\mathbf{Q}$. Collecting ladder series of the same renormalizations, one further enhances Γ_s . If the enhancement is strong enough, one can keep only this term and neglect the interaction at small momentum transfer and the charge component of the interaction near $\mathbf{Q}$. Then one arrives at the effective 4-fermion spin-spin interaction with momentum transfer near $\mathbf{Q}$. For the 1-band cuprate case

$$H_{eff} = \sum_{k,q,p} \Gamma_s(q) c_{k,z}^\dagger \sigma_{x\gamma} c_{k+q,\gamma} c_{p,\beta}^\dagger \sigma_{\beta\delta} c_{p-q,\delta} \quad (11)$$

By construction, this interaction is attractive in the corresponding spatial channel (d -wave for the cuprates, s^{+-} and, in special cases, d -wave for FeSCs, $d \pm id$ for doped graphene. We illustrate this in Fig. 8. The attractive component has the same spatial structure as in 2nd order calculations, so in this respect the difference between the second order analysis and spin fluctuation approach is only in the magnitude of the attractive interaction. It is customary to use the Ornstein-Zernike form $\Gamma_s = \Gamma / (\xi^{-2} + (\mathbf{q} - \mathbf{Q})^2)$, where ξ is a magnetic correlation length. For large ξ , Γ_s is large for $\mathbf{q}$ near $\mathbf{Q}$. The same strategy has been used to obtain the interaction mediated by SDW or nematic fluctuations.

Superconductivity near a quantum-critical point

At a first glance, the attraction mediated by a soft boson can be made as large as possible by focusing on $\mathbf{q} \approx \mathbf{Q}$ and making ξ larger, i.e., bringing the system closer to a magnetic instability. This is not completely true, however, as in most cases of interest a collective boson can decay into a particle-hole pair, that is the bosonic propagator contains the Landau damping term $|\Omega_m|/\nu_F q$. This leads to new physics, which attracted a substantial interest in recent years (Abanov and Chubukov, 2020; Chubukov et al., 2020; Esterlis and Schmalian, 2019; Wang, 2020). Namely, when projected into the particle-hole channel, boson-mediated interaction gives rise to dynamical self-energy, $\Sigma(k, \omega_m)$. At $\xi = \infty$ and in dimension $D \leq 3$, this self-energy at $k = F$ acquires a non-Fermi liquid form $|\omega_m|^a \text{sign} \omega_m$ with $a < 1$ at small frequencies. In other words, the same interaction that gives rise to the pairing, also gives rise to incoherent non-Fermi liquid (NFL) behavior. Whether or not superconductivity occurs in this situation depends on the outcome of the interplay between strong dynamical pairing interaction and strong fermionic incoherence, which acts again pairing. From

Fig. 8 Two routes to superconductivity (a)—Two electrons attract each other when the 1st polarizes the lattice, and the second is attracted to this region. The pair wave function $\Psi(\mathbf{r})$ of the relative electronic coordinate $\mathbf{r}$, has the full symmetry of the crystal and gives rise to a gap function $\Delta_{\mathbf{k}}$ of the same sign for all momenta $\mathbf{k}$ on the FeSC Fermi surface (green = +). (b) Electrons interact with each other via Coulomb interaction. Shown is an example where the dominant interaction is the magnetic exchange arising between opposite spin electrons due to Coulomb forces. The first electron polarizes the conduction electron gas antiferromagnetically, and an opposite spin electron can lower its energy in this locally polarized region. In this case $\Psi(\mathbf{r})$ has a node at the origin, helping to avoid the Coulomb interaction, and can have either $s_{+/-}$ or $d_{x^2-y^2}$ form, as shown. These two possibilities lead to gap functions of opposite sign on the Fermi surface (orange = -). From Chubukov A.V., Hirschfeld P.J. (2015) *Physics Today*.

theory perspective, fermionic incoherence destroys Cooper logarithm and reduces the tendency to pairing, while the opening of a superconducting gap eliminates scattering at low energies and renders a Fermi liquid behavior. Because incoherence and pairing come from the same interaction, they are intertwined, and in general their characteristic scales comparable.

This issue recently attracted strong interest among both condensed-matter and high-energy theorists. Itinerant quantum-critical systems, analyzed analytically in recent years, include fermions in spatial dimensions $D \leq 3$, two-dimensional (2D) fermions near a SDW and CDW instabilities, $2k_F$ density-wave instability, pair-density-wave instabilities, $q = 0$ instabilities toward a Pomeranchuk order and toward a state with circulating currents, 2D fermions at a half-filled Landau level, generic quantum-critical models with varying critical exponents, Sachdev-Ye-Kitaev (SYK) and SYK-Yukawa models, extensively studied in recent years, strong coupling limit of electron-phonon superconductivity, and even color superconductivity of quarks, mediated by gluon exchange. These problems have also been studied using various numerical techniques (see literature in [Abanov and Chubukov, 2020](#); [Chubukov et al., 2020](#); [Esterlis and Schmalian, 2019](#); [Wang, 2020](#)).

To find the outcome of the interplay between SC and NFL, one needs to analyze the set of coupled integral equations for the fermionic self-energy and the pairing vertex. In most metallic quantum-critical models, the dressed low-energy fermions are fast excitations compared to soft bosons for one reason or another. In this situation, which bears parallels with the Eliashberg theory for electron-phonon interaction, the momentum integration can be carried out exactly, after projecting the pairing interaction into the proper irreducible channel, and to resolve the competition between NFL and superconductivity, one has to solve one-dimensional non-linear integral equation for the gap function $\Delta(\omega_m)$:

$$\Delta(\omega_m) = \pi T \sum_{m'} \frac{\Delta(\omega_{m'}) - \Delta(\omega_m) \frac{\omega_{m'}}{\omega_m}}{\sqrt{(\omega_{m'})^2 + \Delta^2(\omega_{m'})}} V(\omega_m - \omega_{m'}) \quad (12)$$

where $V(\Omega_m)$ is an effective “local” interaction with singular frequency dependence $1/|\Omega_m|^\gamma$. The exponent $\gamma > 0$ depends on the microscopic realization. A small $\gamma = O(1)$ holds for models in $D = 3$ —and for pairing of quarks, mediated by gluon exchange, $\gamma = 1/3$ for 2D models at the onset of a nematic or Ising-ferromagnetic order, and for fermions at a half-filled Landau level, $\gamma \approx 1/2$ for 2D models at the onset of SDW or CDW order, $\gamma \approx 0.68$ for pairing in SYK-type modes with equal number of fermion and boson flavors, $\gamma = 1$ for the pairing mediated by 2D propagating bosons, $\gamma \approx 1.2$ has been suggested for Fe-pnictides, and $\gamma = 2$ describes pairing mediated by an Einstein phonon, in the (properly defined) limit of vanishing Debye frequency.

The analysis of (12) shows that NFL in the normal state does not prevent pair formation below a certain T_p , whose value depends on γ , but in a non-critical way ([Fig. 9](#)). It is less certain whether T_p is a true superconducting transition temperature or onset temperature for pairing of still incoherent fermions. In the latter case, the actual T_c is smaller than T_p , and in between T_c and T_p the system displays preformed pair behavior.

Strong coupling limit

Superconductivity in the strong coupling limit have been mostly studied for fermions doped into a Mott insulator. These doped fermions form a small Fermi surface, whose area scales as doping x rather than $1 - x$ expected for a metal with the same number of fermions. A highly non-trivial superconductivity mediate by topological skyrmion excitations has been proposed in the context of superconductivity near Chern insulating regime in TBG ([Khalaf et al., 2021](#)). Another research direction is superconductivity near the boundary to the Mott phase in systems like C_{60} .

Fig. 9 The onset temperature of the pairing, T_p , as a function of γ . From Abanov A.R., Chubukov A. V. (2020) *Physical Review B* 102: 024524 (and references therein).

Conclusion

Superconductivity is a fascinating subject, which remains at the forefront of research in condensed matter physics in the 21st century. In this Chapter I described several directions of the research over the last two decades, with emphasis on unconventional superconductivity of strongly correlated electrons. Other exciting developments in the field of superconductivity are recent works on Higgs excitations in superconductors, on feedback from superconductivity on electronic spectrum, particularly for strongly correlated electrons (neutron resonance and related stuff), on highly non-trivial superconducting order parameters, which preserve the Fermi surface (called Bogolyubov Fermi surface for this purpose), on odd-frequency superconductivity, and on the interplay between pair formation and a true superconductivity (often called BCS-BEC crossover). Another rapidly growing area of research is the analysis of topological aspects of superconductivity. This last area includes the analysis of topological aspects of the pairing near a quantum-critical point.

Abstract

Electrodynamics of superconductors is primarily the electrodynamics of the Meissner state, a state characterized by zero magnetic induction of a superconducting fraction of conduction electrons. Simultaneously, the Meissner state is characterized by zero resistivity and zero entropy of these electrons. The latter means that the temperature of an ensemble of superconducting electrons is zero as well. Understanding properties of the Meissner state provides a key to understand and predict these and other equilibrium and non-equilibrium properties of superconductors, e.g., properties of the intermediate and mixed states, flux quantization, resistanceless transport current, etc. The reader will see that all these properties have a single and very simple origin: quantization of the angular momentum of the conduction electrons combined into Cooper pairs, and that the electrodynamics of superconductors and superconductivity as a whole is a magnificent manifestation of the boundless ingenuity of Nature and of the power of Physics laws.

Key points

- The electromagnetic and thermal properties of superconductors are dictated by Cooper pairs. On this reason, the electrodynamics of superconductors is primarily the electrodynamics of an ensemble of Cooper pairs.
- By definition of Cooper pairs, the paired electrons orbit their center of mass. The stability of Cooper pairs means that the pairs obey the Bohr-Sommerfeld quantization condition.
- In the Meissner phase (the phase of a superconducting sample with zero magnetic induction B) the magnetic field intensity H is equal to or greater than the intensity of the applied field H_0 .
- The properties of superconductors (zero resistivity, zero magnetic induction, zero entropy, flux quantization, etc.) are governed by the precession of Cooper pairs with quantized angular momentum.
- Due to zero entropy, the temperature of an ensemble of Cooper pairs equal to zero regardless of the temperature of the sample.

Introduction

Superconductivity was discovered in the laboratory of Kamerlingh Onnes as a phenomenon of a sharp drop of electrical resistance in a high purity mercury wire at temperature T below 4.2 K (Kamerlingh Onnes, 1911). An original estimate of the resistance drop was 10^4 times compare to the resistance just above the transition temperature, called the critical temperature T_c , a constant of the superconducting (S) material. Fairly soon it became clear that resistance of a superconductor is not merely a small, but zero. Namely, the current in a closed S circuit represents a persistent current like that caused by electrons bound in atoms.¹ It was also found that the S state exists up to a certain temperature-dependent critical magnetic field $H_c(T)$, which is another characteristic of

[☆]Change History: July 2022. V Kozhevnikov updated the chapter.

¹Persistent current is a current running in a closed circuit without both thermal and radiation losses.

the material. While number of superconductors was (and is) steadily growing, at an early stage it seemed that zero resistivity is the only property distinguishing superconductors from the so-called normal (N) metals.

The second hallmark of superconductivity, the disappearance of thermoelectric effects, was discovered by Walter Meissner (Meissner, 1927). Lack of thermo-e.m.f. suggests that entropy of the S fraction of conduction electrons (called “superconducting electrons”) is zero. If so, then superconductivity can be a previously unknown thermodynamic state of matter characterized by complete ordering of superconducting electrons. Gorter and Casimir used zero entropy as the base postulate of their two-fluid model (Gorter and Casimir, 1934), a seminal thermodynamic theory addressing properties of superconductors in zero field. On the other hand, a non-zero thermo-e.m.f. looks incompatible with zero resistivity of the S state, since otherwise it would lead to an infinite current and therefore to an instantaneous restoration of the N state.

The idea of the new thermodynamic state was brilliantly confirmed in a so-called Meissner effect independently discovered by Meissner and Ochsenfeld² (Meissner and Ochsenfeld, 1933) and Ryabinin and Shubnikov (Ryabinin and Shubnikov, 1934). It was found that, apart from zero resistivity and zero entropy, superconductivity is also characterized by zero magnetic induction B regardless on the history of the field application. Hence, a sample in the Meissner state (MS) represents a perfect diamagnetic, i.e., its magnetic susceptibility χ and permeability $\mu_m (= 1 + 4\pi\chi)$ are equal to $-1/4\pi$ and zero, respectively. Important to note that (i) like in regular diamagnetics, in the MS χ and therefore μ_m do not depend on the sample temperature T and the applied field H_0 ; and (ii) if the first two “big zeroes” of superconductivity take place in samples of any shape, connectivity and purity, the third zero ($B = 0$ or the Meissner effect) is observed only with sufficiently pure singly connected samples of an ellipsoidal shape.

It was found that there are two kinds of superconductors distinguishing by the sign of the S/N interphase energy also called surface tension. Materials with positive and negative surface tension are referred to as type-I and type-II superconductors, respectively. All type-I superconductors are elementary metals, while type-II materials, with very few exceptions, are alloys and multicomponent compounds. A sample of type-I material can be made behaving like type-II superconductor by introducing impurities and/or reducing the sample size, e.g., by decreasing the thickness of a film sample. However, the opposite is not possible. Other really astonishing properties, such as the flux quantization, Josephson effect and others, were discovered in 1960s and later.

A search for the source of the superconductivity phenomenon culminated in a ground braking theoretical discovery of Leon Cooper (1956), who shown that even a weak attraction can lead to formation of stable electron pairs called Cooper pairs. The origin of attraction lays in the medium polarization occurring due to electron-lattice interaction, as it was first suggested by Fröhlich (1950) and discussed in the BCS theory (Bardeen, Cooper, Schrieffer, 1957). Cooper’s prediction was irrefutably confirmed in experiments (Deaver and Fairbank, 1961 and many others).

Cooper pairs profoundly alter the medium electrodynamics. The physics behind these alterations is the subject of this chapter.

The chapter consists of three sections: Meissner state, Flux quantization and Total current, and a brief summary. References to literature for further reading are given at the end. The cgs units are used because these units are the most appropriate for discussing electrodynamics of continuous media.³ In view of the space limit only key references are provided.

Meissner state

Definitions

The MS is an equilibrium S state defined as the state with $B = 0$ throughout the sample volume V . Alike, the MS can be defined as the state with $\mu_m = 0$ or $\chi = -1/4\pi$ all over V .

The MS takes place in sufficiently pure massive and simply connected samples of an ellipsoidal shape in the applied field $H_0 < H_{c1}(1 - \eta)$. Here H_{c1} is the lower critical field of type-II superconductors equal to the thermodynamic critical field H_c in the type-I counterparts, and η is the demagnetizing factor⁴ with respect to an ellipsoidal axis parallel to H_0 . A sample is considered as massive if its minimal size significantly exceeds a so-called penetration depth λ , a width of the surface layer where B decays from the induction of external field near the sample surface B_{ext} to zero in the sample interior.

A unique feature of the ellipsoidal bodies in a static magnetic field is uniformity of the field intensity $\mathbf{H}$ (also called the magnetizing force, field strength, etc.) throughout their volume, as it was first shown by Poisson (Poisson, 1824) and discussed by Maxwell (Maxwell, 1873). The intensity $\mathbf{H}$ is responsible for magnetization $\mathbf{I} (= \chi\mathbf{H})$. Depending on a demagnetizing field $H_d (= 4\pi\eta\mathbf{I})$, in diamagnetics $\mathbf{H} (= \mathbf{H}_0 - \mathbf{H}_d)$ is greater than or equal to $\mathbf{H}_0$ in magnitude, and its direction can differ from that of the applied field. $\mathbf{H}$ is the field acting on “native” (belonging to the body) charges, whereas the induction $\mathbf{B}$ is the field acting on a “foreign” (extraneous) charges.⁵ Contrarily to $\mathbf{B} (= \mathbf{H} + 4\pi\mathbf{I})$, the average of microscopic fields caused by all native charges, $\mathbf{H}$ does not include the field due to the charge in question.⁶ Respectively, in any medium $\mathbf{H}$ differs from $\mathbf{B}$. On the contrary, in a free space (vacuum) $\mathbf{I} = 0$ and, consequently, $\mathbf{H} = \mathbf{B}$.⁷

²An active promoter of this experiment was von Laue.

³Different dimensions of the induction $\mathbf{B}$ and the intensity $\mathbf{H}$ of the magnetic field in the SI unit system, make this system in its current form inapplicable for this purpose.

⁴The demagnetizing factors are determined by relationship of the ellipsoidal axes. Respectively, η -s are defined only for the ellipsoidal bodies.

⁵On that reason the field measured by a prob charge, e.g., in μSR , is B , whereas in magnetic resonances the measured or controlling field is H .

⁶Here, the charge should be understood as the current caused by all types of microscopic movement, including the spinning one, of a given charge.

⁷Important that this is not just a mathematical coincidence, but a physical identity. This implies that in any system of physical units the dimensions of $\mathbf{B}$ and $\mathbf{H}$ must be the same.

Fig. 1 Induction $\mathbf{B}$ (A) and intensity $\mathbf{H}$ (B) of the magnetic field inside and outside of a long cylindrical sample in the Meissner state when the field $\mathbf{H}_0$ is applied transversely to its longitudinal axis. For this sample/field configuration $\eta = 1/2$. Inside the sample $\mathbf{B} = 0$ and $\mathbf{H} = \mathbf{H}_0/(1 - \eta) = 2\mathbf{H}_0$; outside it $\mathbf{H} = \mathbf{B}$ and far away $\mathbf{H}_0 = \mathbf{B}_0$. Shadowed circle is a cross-section of the sample oriented perpendicular to the page.

At the sample boundary the normal component of the intensity H_n undergoes a discontinuity $\Delta H_n = 4\pi I_n$, where I_n is the magnitude of the normal component of magnetization $\mathbf{I}$. Correspondingly, the intensity can be viewed as a potential field created by magnetic charges sitting on the boundary and having a surface density I_n . On the other hand, the intensity inside the sample, i.e. in any volume element dV not crossed by the sample boundary, represents a solenoidal or divergenceless field, which, therefore, can be described by a vector potential. As an example, Fig. 1 schematically shows the induction $\mathbf{B}$ and the intensity $\mathbf{H}$ of the magnetic field in and out of a sample with $\eta = 1/2$ when it is in the MS.⁸

If $\mathbf{H}_0$ is parallel to an axis of the ellipsoidal sample in the MS, $\mathbf{H} = \mathbf{H}_0/(1 - \eta)$, where η is the demagnetizing factor about this axis. If $\mathbf{H}_0$ is not parallel to either axis, $\mathbf{H}$ is the vector sum of the intensities relative to each axis. At any orientation of $\mathbf{H}_0$ with respect to the sample in the MS, inside it the magnitude of intensity $\mathbf{H}$ is less than H_{c1} .

After all, a very important property of the MS follows from the Law of the symmetry of time reversal, mandatory for any (either classical or quantum) equilibrium state. According to this Law, no total current can occur in the equilibrium state⁹ and therefore all currents in the MS must be compensated.

In samples with $\eta = 0$, referred to as the samples of cylindrical geometry, the outer field due to the magnetized sample is absent and respectively $\mathbf{H} = \mathbf{H}_0$ both inside and outside the sample. Such samples can be, e.g., long cylinders, infinite slabs or wide ribbon-like foils in $\mathbf{H}_0$ parallel to their generating line.¹⁰ Here our discussion of the MS will be limited by the cylindrical samples.

In this case the magnetic moment $\mathbf{M}$ of the sample is

$$\mathbf{M} \equiv \chi V \mathbf{H} = -\frac{V}{4\pi} \mathbf{H}_0 \quad (1)$$

and the sample magnetic energy E_m is

$$E_m \equiv -\int \mathbf{M} \cdot d\mathbf{H}_0 = -\frac{\mathbf{M} \cdot \mathbf{H}_0}{2} = \frac{V H_0^2}{8\pi}. \quad (2)$$

By virtue of the energy conservation, in the cylindrical samples $E_m = \Delta T$, where the latter is the field-induced change of the kinetic energy of electrons. As an example, graphs for $\mathbf{M}$ vs $\mathbf{H}_0$ for a type-I superconductor with $\eta = 0$ are shown in Fig. 2.

Cooper pairs

The Cooper pairs are defined as a correlated state of two conduction electrons with zero net kinetic linear momentum with respect to their center of mass and zero net spin. The latter condition stems from the requirement of thermodynamics since the free energy of a system of units with zero spin is lesser than it would be if the spin is not zero. The same condition justifies the thermodynamic advantage of the electron pairing since it allows to null the spin.

Zero net kinetic linear momentum and stability of the pairs mean that the paired electrons orbit their center of mass like, e.g., stars in a binary star. Therefore, each Cooper pair possesses the angular momentum $\mathbf{l}$ and the magnetic moment $\boldsymbol{\mu} = \gamma \mathbf{l}$, where γ is the gyromagnetic ratio. As measured by Kikoin and Goober, 1938, γ in superconductors equals its classical value $e/2mc$. Here m and e are mass and charge of one electron, respectively, and c is the electromagnetic constant of the cgs unit system equal to speed of light. This confirms that the “superconducting” electrons are effectively spinless.

⁸The London theory, adopted for description of the MS in the Ginzburg-Landau and BCS theories, is based on an assumption that in superconductors the magnetic susceptibility μ_m and the dielectric permittivity ϵ_e are unity and therefore $\mathbf{B} = \mathbf{H}$. However, this is only true in a vacuum.

⁹The time transformation $t \rightarrow -t$ changes the direction of magnetic moment of a system with total current and therefore such a system can not be in the equilibrium state by definition.

¹⁰Any sample with $\eta = 0$ can be broken for a large number of identical thin circular cylinders parallel to $\mathbf{H}_0$.

Fig. 2 Magnetic moment of a $2.9\text{--}\mu\text{m}$ thick indium film in the parallel field H_0 measured at constant temperatures, as indicated. For this sample $\eta = 0$ and $\mathbf{H} = \mathbf{H}_0$. The data were taken with the sample cooled in zero field (arrow up for 2.0 K) and in the field exceeding H_c (arrow down for 2.0 K). Hysteresis at the S/N transition is the supercooling effect caused by the positive S/N surface tension. The film geometry is shown in the insert. After Kozhevnikov V, Suter A, Prokscha T, and Van Haesendonck C (2020) *Journal of Superconductivity and Novel Magnetism* 33: 3361; reprinted with permission from Springer Nature.

Stability of the pairs also means that the orbital motion of the paired electrons occurs without energy dissipation. Therefore they must obey the Bohr-Sommerfeld quantization condition. At the same time, one should bear in mind that to meet the law of momentum conservation, in a magnetic field the linear momentum should be taken in a generalized form. Hence, the quantization condition for the single Cooper pair is

$$\oint \tilde{\mathbf{p}}_{cp} \cdot d\mathbf{l} = 2\pi R \tilde{p}_{cp} = 2\pi \tilde{l}_{cp} = nh, \quad (3)$$

where $\tilde{\mathbf{p}}_{cp}$ and $\tilde{l}_{cp}$ are the generalized linear and angular momentum of the pair, respectively, R is the radius of orbital motion of paired electrons, h is the Planck constant, and n is a non-negative integer ($n = 0, 1, 2, \dots$).

By definition of $\tilde{\mathbf{p}}$, the generalized linear momentum of the paired electrons $\tilde{\mathbf{p}}_{cp}$ is

$$\tilde{\mathbf{p}}_{cp} = \tilde{\mathbf{p}}_1 + \tilde{\mathbf{p}}_2 = \left(m\mathbf{v}_1 + \frac{e\mathbf{A}_1}{c} \right) + \left(m\mathbf{v}_2 + \frac{e\mathbf{A}_2}{c} \right) \quad (4)$$

where $\mathbf{v}$ is the electron velocity and $\mathbf{A}$ is the vector potential of the field acting on the electron, i.e. of the intensity $\mathbf{H}$; subscripts 1 and 2 denote the quantities related to the first and second electron in the pair.

In the ground state, i.e. at zero field and temperature, n in Eq. (3) takes the lowest value $n = 0$ and $\tilde{\mathbf{p}}_{cp}$ is the sum of kinetic linear momentums $\mathbf{p}(=m\mathbf{v})$ of electrons. Hence,

$$\left(\tilde{\mathbf{p}}_{cp} \right)_0 = \left(\mathbf{p}_{cp} \right)_0 = \mathbf{p}_{10} + \mathbf{p}_{20} = 0 \quad (5)$$

where subscript 0 denotes the zero field.

The last part of Eq. (5) is identical to the definition of Cooper pair. The first part of this equation $\left[\left(\tilde{\mathbf{p}}_{cp} \right)_0 = 0 \right]$ is a modified London's rigidity, originally formulated for a single superconducting electron (London, 1960). Also, Eq. (5) implies that the center of mass of the pair is at rest with respect to the sample.

The motion of electrons in one Cooper pair at zero field and temperature is schematically shown in Fig. 3. The orbit diameter $2R_0$ corresponds to the coherence length ξ_0 of the BCS theory and ξ of the Ginzburg-Landau (GL) theory (Ginzburg and Landau, 1950), which are close to each other at these conditions.

One more important property at zero field is related to the ensemble of Cooper pairs: due to symmetry, the total magnetic moment of all pairs (the magnetic moment of the sample) is zero, i.e.

Fig. 3 Schematics of a single Cooper pair at zero field and temperature. ι_0 and μ_0 are the angular momentum and the magnetic moment of the pair, respectively; γ is the gyromagnetic ratio; p_{10} and p_{20} are the kinetic linear momentums of electrons; J_0 is the current caused by the orbital motion of electrons round their center of mass; R_0 is the orbit radius; red dot designates the center of mass of the pair.

$$M_0 = \sum \mu_0 = 0 \quad (6)$$

where summation is taken over all pairs.¹¹

In view of uniformity of the bulk properties of the MS, Eq. (6) holds for the unit volume as well as for a physically infinitesimal volume element dV . The latter in superconductors is defined as a volume, which size is much smaller than the size of the volume taken by the S phase and much larger than the spatial inhomogeneity of microscopic currents, i.e. R_0 . We remind that Cooper pairs are heavily overlap, but it affects neither stability, no mobility of the pairs. Taking into account the wave side of the electron nature, this fact is similar as the overlapping of myriads of electromagnetic waves does not prevent us from seeing objects or enjoying music broadcast from the other side of the globe.

Now it is rather obvious what happens when the magnetic field is turned on: Cooper pairs precess. Let us see how does it go.

In the field, each of the paired electrons (as well as all other charges constituting the sample) experiences the action of the Lorentz force.¹² In absence of the applied electric field,¹³ this force is

$$\mathbf{F} \equiv \frac{d\mathbf{p}}{dt} = -\frac{e}{c} \left(\frac{\partial \mathbf{A}}{\partial t} \right) + \frac{e}{c} \mathbf{v} \times \mathbf{H} = -\frac{e}{c} \left(\frac{\partial \mathbf{A}}{\partial t} \right) + \frac{e}{c} \mathbf{v} \times (\nabla \times \mathbf{A}) \quad (7)$$

Here t is time, $\mathbf{A}$ is the vector potential of the field $\mathbf{H} (= \nabla \times \mathbf{A})$, and $\mathbf{v}$ is the electron velocity, which magnitude is about the same as the Fermi velocity v_F (the maximum difference between v and v_F is on the order of a percent).

Important to note that since inside real bodies $\mathbf{B}$ and $\mathbf{H}$ are different, one has to distinguish the vector potential for $\mathbf{H}$ and for $\mathbf{B}$. In our notations $\mathbf{A}$ is the vector potential of the intensity $\mathbf{H}$ inside the sample. Below we will see how $\mathbf{A}$ is related to the vector potential $\mathbf{A}_B$ defined by the relationship $\mathbf{B} = \nabla \times \mathbf{A}_B$. As usual, the supplementary condition $\nabla \cdot \mathbf{A} = 0$ is presumed.

The first term in the right-hand side of Eq. (7) is an electric force $\mathbf{F}_E$ caused by the changing magnetic field.

Corresponding vortex electric field $\mathbf{E}$ is defined as

$$\mathbf{E} \equiv \frac{\mathbf{F}_E}{e} = -\frac{1}{c} \left(\frac{\partial \mathbf{A}}{\partial t} \right). \quad (8)$$

As with bound electrons in conventional materials, the electric field $\mathbf{E}$ (existing while the magnetic field is changing) does the work resulting in a change of kinetic energy of electrons and in the appearance of an induced magnetic moment in each pair.

Specifically, when the vector potential changes from zero to $\mathbf{A}$, which corresponds to the intensity change from zero to $\mathbf{H}$, the velocity of electrons in the pair is changed from $\mathbf{v}_0$ to $\mathbf{v}'$. The difference $\mathbf{v}_i = \mathbf{v}' - \mathbf{v}_0$ is the velocity induced due to the applied magnetic field. Integrating Eq. (8) over time, one obtains

$$\mathbf{v}_i = -e \frac{\mathbf{A}}{cm}. \quad (9)$$

This is a very important formula. It shows that $\mathbf{v}_i$ is parallel to $\mathbf{A}$. Therefore, since by definition $\mathbf{A}$ lies in the plane perpendicular to $\mathbf{H}$, $\mathbf{v}_i$ and therefore the induced current also lies in the plane transverse to $\mathbf{H}$. On the other hand, the induced current makes a closed loop (it cannot leave the sample) and the loop must be circular due to rotational symmetry stemming from uniformity of $\mathbf{H}$ (all directions in the transverse plane are equivalent); therefore lines of the vector potential make the circular loops either. Hence, an appropriate gauge for the vector potential of $\mathbf{H}$ is the circular one, namely $\mathbf{A} = \mathbf{H} \times \mathbf{r}/2$. The lines of this vector potential are shown in Fig. 4.

Fig. 4 Lines of the vector potentials $\mathbf{A}$ of the circular gauge for a uniform magnetic field $\mathbf{H}$ directed toward the reader (along the z -axis); $\hat{x}$ and $\hat{y}$ are unit vectors along x and y axes, respectively. $\mathbf{r}$ is a radius vector lying in xy plane. As for all vector fields, the line of $\mathbf{A}$ is the directional line tangential to the vector $\mathbf{A}$ in each of its point.

¹¹Note that Eq. (6) resembles the definition of a diamagnetic atom, where each electron has a non-zero orbital momentum, while the momentum of the atom is zero.

¹²The action of a magnetic field on atomic electrons and nuclei results in the usual diamagnetic response; its action on unpaired conduction electrons causes a weak Landau diamagnetism.

¹³A static electric field does not penetrate the superconducting sample due to the screening effect of always present “normal” electrons.

Thus, since $e < 0$, Eq. (9) indicates that the current induced in each Cooper pair creates a magnetic moment directed opposite to $\mathbf{H}$, i.e. the induced moment is always diamagnetic, in accord with requirements of thermodynamics and the time reversal symmetry. This also means that diamagnetism (both in normal and superconducting materials) results from the changing magnetic field in full consistency with the laws of the classical physics.

Next, like in regular diamagnetics, in Eq. (9) the time has dropped out implying that the induced velocity $\mathbf{v}_i$ is indifferent to the rate of the field change.

After all, Eq. (9) implies that the vector potential in superconductors is not gauge-invariant since a change in $\mathbf{A}$ changes the induced moment and because $\mathbf{A}$ of any but the circular gauge does not possess the necessary rotational symmetry. However, this is not surprising¹⁴ since the gauge invariance is inapplicable to quantities defined by the vector potential in explicit form. Non-fulfillment of the gauge-invariance in superconductors is an additional confirmation of the fact that the vector potential is a real and primary characteristics of the magnetic field, as demonstrated by the Aharonov-Bohm effect (Ehrenberg and Siday, 1949; Aharonov and Bohm, 1959).

The second term in the right hand side of Eq. (7) is termed the magnetic force $\mathbf{F}_M$. It is perpendicular to the electron velocity and therefore does no work. Hence, $\mathbf{F}_M$ does not affect the electron kinetic energy and the magnitude of its magnetic moment. On the other hand, since the uniform magnetic field cannot change position of the pair's center of mass, $\mathbf{F}_{M1} = -\mathbf{F}_{M2}$ (those are the magnetic forces acting on the 1st and 2nd electron in the pair), and also $\mathbf{F}_{M1}$ and $\mathbf{F}_{M2}$ are non-central forces. Hence, they make a couple resulting, due to non-zero $\boldsymbol{\iota}_0$, in precession of $\boldsymbol{\mu}_0$ relative to the vector $\mathbf{H}$, as schematically shown in Fig. 5.

The angular velocity of precession, referred to as Larmor frequency, is

$$\boldsymbol{\omega} = -\gamma\mathbf{H} = -\frac{eg_L}{2mc}\mathbf{H}, \quad (10)$$

where g_L is the Lande factor. As mentioned, in superconductors γ takes the classical value, i.e. $g_L = 1$.

As follows from the Larmor theorem, if $v_i \ll v_0$, precession of the electron orbit is equivalent to the undisturbed orbital motion at the field absence (i.e. with fixed $\boldsymbol{\mu}_0$ and R_0) plus an additional (field induced) circular motion with the angular velocity $\boldsymbol{\omega}$ and radius r proportional to R_0 , which leads to appearance of the diamagnetic moment $\boldsymbol{\mu}_{cp}$. On the other hand, the invariability of $\boldsymbol{\mu}_0$ means that Eq. (6) is valid both in the absence and presence of the magnetic field. This can be also understood basing on the fact that precession is an inertia-free motion and therefore all pairs precess synchronously,¹⁵ i.e. without changing their mutual orientation.

Thus, we arrive to conclusion (following both from consideration of the action of Lorentz force Eq. (7) and from the Larmor theorem) that the net effect of the magnetic field is the induced circular motion of the paired electrons in the planes transverse to $\mathbf{H}$. On the other hand, as it is known for any kind of cyclic motion in magnetic field, the changing $|\mathbf{H}|$ changes the magnitude of $\mathbf{v}_i$ only, i. e. the radius of the induced motion r does not depend of the field provided that $v_i \ll v_0$.

Fig. 5 Schematics of the Cooper pair precession in the magnetic field $\mathbf{H}$. Vectors $\boldsymbol{\iota}_0$ and $\boldsymbol{\mu}_0$, current J_0 and radius R_0 are the same quantities as those at zero field shown in Fig. 3. A dot-dashed circle designates the path of the tip of the precessing $\boldsymbol{\iota}_0$. A dashed blue circle depicts the field-induced current J_{cp} ; it is also a line of the vector potential directed opposite to the current J_{cp} . $\mathbf{A}$ and $\mathbf{v}_i$ designate the vector potential and the induced velocity of one electron, respectively; r is the radius of the induced current; $\boldsymbol{\mu}_{cp}$ is the induced magnetic moment of the pair. Designated by a single arrow $\mathbf{A}$ and $\mathbf{v}_i$ are proportional but not equal. After Kozhevnikov V (2021) *Journal of Superconductivity and Novel Magnetism* 34: 1979; reprinted with permission from Springer Nature.

¹⁴Recall that the gauge-invariance does not hold in the London and BCS theories.

¹⁵Also, as it is shown below, the induced circular motion of the paired electrons occurs in phase.

Fig. 6 A cross sectional view of a conventional diamagnetic sample showing induced bound currents caused by precession of the atomic electron orbits; the field is directed into the page. This picture is similar to the induced currents caused by precession of Cooper pairs in a superconducting sample in the Meissner state. After the textbook of Tamm IE, *Fundamentals of the Theory of Electricity*, 9th edn. Moscow: Mir, 1979, reprinted with permission from Mirtitles.

One can also show that $\tilde{\mathbf{p}}_{cp}$ does not depend on the magnetic field either, namely

$$\tilde{\mathbf{p}}_{cp} = \tilde{\mathbf{p}}_1 + \tilde{\mathbf{p}}_2 = \tilde{\mathbf{p}}_{10} + \tilde{\mathbf{p}}_{20} = 0. \quad (11)$$

Hence, the modified London's rigidity holds both in zero and non-zero field. Below we will see that it also holds at non-zero temperature.

The induced currents in superconductors in the MS (and in other equilibrium S states) are qualitatively identical to the induced bound currents in regular diamagnetics schematically shown in Fig. 6. In our case, like in the normal materials, the induced currents mutually compensate each other in the sample bulk, leaving an uncompensated surface current caused by electrons bound in Cooper pairs with resting centers of inertia. Then the magnetic moment of the sample is exactly the same as the moment produced by a continuous (circumferential) surface current.

Now we are ready to calculate magnetic proprieties of our cylindrical sample in the MS.

After turning on the applied field $\mathbf{H}_0$, the field intensity and the vector potential inside the sample after a short relaxation time become $\mathbf{H}$ and $\mathbf{A}$, respectively. Then, using Eq. (9), we write.

$$m\mathbf{v}_i = -\frac{e}{c}\mathbf{A} = -\frac{e}{2c}\mathbf{H} \times \mathbf{r}. \quad (12)$$

Hence,

$$m\boldsymbol{\omega} = -\frac{e}{2c}\mathbf{H}, \quad (13)$$

where $\boldsymbol{\omega} = (\mathbf{r} \times \mathbf{v}_i)/r^2$ is the angular velocity of the induced circular motion of the paired electrons.

Taking into account that $e < 0$, Eq. (13) reads that $\boldsymbol{\omega}$ is parallel to $\mathbf{H}$ and its magnitude is

$$\omega = \frac{v_i}{r} = \frac{e}{2mc}H. \quad (14)$$

Comparing with Eq. (10) we see that ω equals the classical Larmor frequency ($g_L = 1$). This confirms that we really deal with the precession of paired electrons with zero total spin, since non-paired electrons (as any other charge) in a magnetic field circulate with a so-called cyclotron frequency $\omega_c = (e/mc)H$.

The induced current per one electron in the pair J_i is

$$J_i = \frac{e}{2\pi}\omega = \frac{e^2}{4\pi mc}H. \quad (15)$$

As follows from Eqs. (14) and (15), neither induced angular velocity ω , nor the induced current J_i depend on r . However, this is not the case for the induced magnetic moment and the corresponding change of kinetic energy of the paired electrons: they both depend on r^2 . On the other hand, r for Cooper pairs with different orientation of $\boldsymbol{\mu}_0$ is different. So what we want to know is the mean square $\langle r^2 \rangle$, which we will denote as r_i^2 .

Using Eq. (15), the magnitude of an average induced magnetic moment per one electron in Cooper pairs is

$$\mu_i = \frac{1}{c}J_i\pi r_i^2 = \frac{e^2 r_i^2}{4mc^2}H = \frac{e^2 n_s 4\pi}{mc^2} \left(\frac{r_i}{2}\right)^2 \frac{H}{4\pi n_s} = \frac{(r_i/2)^2}{\lambda_L^2} \frac{H}{4\pi n_s}. \quad (16)$$

where n_s is a number density of superconducting (i.e. paired) electrons and λ_L is so-called London penetration depth defined as

$$\lambda_L = \left(\frac{mc^2}{4\pi n_s e^2}\right)^{1/2} = \left(\frac{m_{cp} c^2}{4\pi n_{cp} q_{cp}^2}\right)^{1/2}, \quad (17)$$

where $m_{cp} = 2m$, $q_{cp} = 2e$ and $n_{cp} = n_s/2$ are the mass, charge and number density of Cooper pairs, respectively.

Since induced magnetic moments in all Cooper pairs are parallel, the magnitude of the magnetic moment of our sample is

$$M = n_{cp} V \mu_{cp} = \frac{(r_i/2)^2}{\lambda_L^2} \frac{V}{4\pi} H = \frac{(r_i/2)^2}{\lambda_L^2} \frac{V}{4\pi} H_0. \quad (18)$$

Comparing this result with Eq. (1), we see that the rms radius of the induced motion of the paired electrons is

$$r_i = 2\lambda_L. \quad (19)$$

Since r does not depend on the field, r_i and therefore λ_L do not depend on the field either.

Next, basing on Eq. (6) one can show that, like in regular diamagnetics, the change of kinetic energy of the superconducting electrons ΔT is the sum of the field-induced kinetic energies of each of these electrons, i.e.

$$\Delta T = E_k = \varepsilon_i n_s V = \varepsilon_{cp} n_{cp} V, \quad (20)$$

where $\varepsilon_{cp} = 2\varepsilon_i$ is the average kinetic energy of the induced motion of electrons in one pair.

Using Eq. (14), we write

$$\varepsilon_i = \frac{mv_i^2}{2} = \frac{e^2 H^2 r_i^2}{8c^2 m} = \left(\frac{(r_i/2)}{\lambda_L} \right)^2 \frac{H^2}{8\pi n_s}. \quad (21)$$

Thus, taking into account Eq. (19), the change of kinetic energy of the paired electrons is

$$\Delta T = \varepsilon_i n_s V = \left(\frac{(r_i/2)}{\lambda_L} \right)^2 \frac{H^2}{8\pi} V = \frac{H^2}{8\pi} V. \quad (22)$$

In our sample $H = H_0$ and, according to the energy conservation, $\Delta T = E_m = H_0^2 V / 8\pi$ (see Eq. 2). Hence, our description meets the Law of energy conservation.

Next, we calculate the gyromagnetic ratio coming from its definition. Using Eqs. (14) and (16) we write

$$\gamma \equiv \frac{M_i}{L_i} = \frac{\mu_i n_s V}{l_i n_s V} = \frac{\mu_i}{mv_i r_i} = \frac{e^2 r_i^2 H}{4mc^2} \frac{2c}{er_i^2 H} = \frac{e}{2mc}, \quad (23)$$

where M_i and L_i are magnitudes of the induced magnetic moment and of the induced angular momentum of the sample, respectively; and l_i is an average field-induced angular momentum per one electron.

We see that γ is fully consistent with the experimental result of I. Kikoin and Goobar.

After all, calculate the induction in the sample interior. Using Eqs. (16) and (19), and the fact that μ_i is negative, we obtain

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{I} = \mathbf{H} + 4\pi(\boldsymbol{\mu}_i n_s) = \mathbf{H} - 4\pi \frac{\mathbf{H}}{4\pi n_s} n_s = 0, \quad (24)$$

in agreement with the result of Meissner and Ochsenfeld and of Rjabinin and Shubnikov.

Correspondingly, the magnetic permittivity $\mu_m \equiv B/H$ and susceptibility per unit volume χ of the S phase are zero and $-1/4\pi$, respectively.

Naturally, due to microscopic character of the induced currents, there is no problem in establishing the Meissner condition ($B=0$) in samples/domains of any shape, as soon as the field $\mathbf{H}$ is uniform. The latter is indeed so in ellipsoidal samples, regardless whether they are in the MS or in the inhomogeneous equilibrium states, i.e., in the mixed state of type-II and in the intermediate state of type-I superconductors.

This explains why the Meissner state is observed only in the ellipsoidal bodies, as well as the plenty domain shapes observed in the intermediate state.

The above consideration applies to the samples cooled in zero field (ZFC), whereas the Meissner effect is about both the ZFC and FC (field-cooled) samples. So, what happens in the latter case?

Upon lowering temperature below $T_c(H_0)$ in the fixed field $H_0 < H_{c1}(1 - \eta)$, a temperature dependent fraction of conduction electrons condenses forming stable Cooper pairs. This means that speed of these electrons drops from v_F to v_0 , each pair starts orbiting its center of mass and, being in the field, the pairs precess. Like in regular diamagnetics, the latter leads to establishing magnetization $\mathbf{I}$, the field intensity $\mathbf{H} = \mathbf{H}_0 - 4\pi\eta\mathbf{I}$ and the induction $\mathbf{B} = \langle \mathbf{h} \rangle = \mathbf{H} + 4\pi\mathbf{I}$, where $\langle \mathbf{h} \rangle$ is the average microscopic field. Hence, after the short relaxation time needed to establish the intensity $\mathbf{H}$, the environment inside the FC sample becomes the same as that in the ZFC sample. Thus, the given description meets the Meissner effect indeed.¹⁶

One more remark. As mentioned above, radius of the electron orbit R_0 in precessing Cooper pairs is fixed (i.e. it does not depend on the field) and the Larmor theorem is exact if $v_i \ll v_0$. Taking typical value of $H_{c1} \sim 100$ Oe and $\lambda_L \sim 10^{-6}$ cm, from Eq. (12) one finds $v_i \sim 10^2$ cm/s, which is six orders of magnitude less than $v_0 \approx v_F \sim 10^8$ cm/s. So, there is no doubt that R_0 does not depend on the field. On the other hand, since r_i and R_0 are quantities of the same or close order of magnitude, this estimate implies that $\omega \ll \omega_0 \equiv v_0/R_0$, i.e. the precession is very slow.

Microscopic whirls

Now, let us reconstruct the current structure of the MS. We understand that all induced currents form identical circular loops with the rms radius r_i laying in parallel planes transverse to $\mathbf{H}$. How these currents are arranged with respect to each other?

¹⁶The standard description of the Meissner effect is based on the London theory in which this effect is achieved by postulating $B = 0$.

Coming from symmetry, one can expect either complete chaos or complete order. Since the system of the ordered currents has lesser free energy, the second option prevails. This is consistent with experimental results of Keesom and Kok (1934) that entropy of the sample in the S state is less than that in the N state.

An ordered structure of identical circular currents laying in the planes transverse to $\mathbf{H}$ possesses the maximum symmetry if the currents form a 2D hexagonal lattice of cylindrical micro-whirls resembling densely packed and tightly “wound” micro-solenoids parallel to each other and to $\mathbf{H}$. Length of each whirl/solenoid equals the sample size along direction of $\mathbf{H}$ and its rms diameter is $2r_i = 4\lambda_L$. Since the solenoids are parallel, they do not interact. In addition, since the currents are given by the field-induced circular motion of the paired electrons, the complete ordering implies that in all Cooper pairs this motion is in phase.¹⁷

Just a few facts supporting this statement. (i) The internal energy of the cylindrical sample in the MS is just the sum of kinetic energies ε_i (Eq. 22) and it does not contain the term(s) responsible for interaction. (ii) In pure type-II superconductors Abrikosov vortices¹⁸ make the hexagonal lattice, as was first observed by Essmann and Träuble (Essmann and Träuble, 1967). (iii) An experimental evidence showing that the Abrikosov vortices do not interact with each other in pure samples (Kozhevnikov et al., 2018).

Naturally, the complete ordering of the field-induced currents together with Eq. (6) mean that entropy of the ensemble of Cooper pairs S_{cp} is zero, exactly as it takes place for the magnetic part of entropy in regular diamagnetics. Therefore the given theoretical interpretation, referred to as a micro-whirls (MW) model, is consistent with the absence of the thermoelectric effects in superconductors and justifies the postulate of zero entropy of superconducting electrons of the two-fluid model of Gorter and Casimir.

One more detail about the micro-whirls. A spacing between current loops Δ along the whirl axis is a universal quantity¹⁹ equal to

$$\Delta = \frac{2e^2}{mc^2} = 5.6 \cdot 10^{-13} \text{ cm} \approx 6 \text{ fm}. \quad (25)$$

So Δ is about a tripled size of a proton (1.7 fm) and therefore the whirls are similar to very tightly wound solenoids indeed.

An important feature of a single whirl is that it is characterized by two microscopic quantities with dimension of length. Those are the radius of the orbital motion R_0 and the radius of the field-induced circular motion r_i . As mentioned, r_i is proportional to R_0 , both radii do not depend on the field and the ratio r_i/R_0 is a constant of superconducting material. However, if vector $\mathbf{r}_i$ always lays in the transverse plane, $\mathbf{R}_0$ is symmetrically distributed over 3D space as follows from Eq. (6). So, like in the Langevin theory of diamagnetism, a mean squared projection of $\mathbf{R}_0$ on the transverse plane $R_\perp^2$ equals $2R_0^2/3$. In other words, $R_\perp$ is an rms radius of a cylinder coaxial to the cylinder with radius r_i and filled by orbiting Cooper pairs. Hence, an individual whirl can be viewed as a “double wall” cylinder with radii $R_\perp$ and r_i .

A parameter of material in the MW model is $\aleph$ (aleph) defined as

$$\aleph = \frac{r_i}{R_\perp}. \quad (26)$$

In materials with $\aleph < 1$ the S/N surface tension is positive and correspondingly such materials represent type-I superconductors. In type-II superconductors the S/N interphase energy is negative and $\aleph > 1$. The cross section of the whirl structure in type-I and type-II superconductors is shown in Fig. 7.

Penetration depth

Another important property of the MS is the penetration depth λ , a width of the surface layer where B decays from $B_{ext}(=B_0=H_0$ for the cylindrical samples) to zero in the sample interior.

According to the London theory, in a sample with a plane boundary (i.e., in the massive cylindrical samples), the induction $B(z)$, where z is the distance from the surface, decays exponentially with the decay constant λ_L . Correspondingly, λ is infinite and an effective penetration depth $\lambda_{eff} = \lambda_L$.²⁰ What is λ in the MW model?

To answer this question one needs to know the angular distribution of μ_0 , which is beyond the scope of the semiclassical consideration employed in the model. One can estimate λ assuming that the boundary of the blue cylinders in Fig. 7 is sharp or the induced current J_i is linear. Then for the plane sample boundary $\lambda = r_i = 2\lambda_L$ and $\lambda_{eff} = \lambda_L/2$. This is, of course, an oversimplified estimate, however in any case in the MW model λ is finite and close to λ_L .

Temperature

All properties discussed so far are related to those for the samples at $T = 0$. However, it is quite obvious that nothing will change if $T \neq 0$.

¹⁷Note the direct analogy with the phase of the quantum-mechanical wave function. The wave functions of all Cooper pairs must be in phase since otherwise there would be a total current forbidden by the time reversal symmetry.

¹⁸The Abrikosov vortices represent holes in the network of the ordered currents of the MS.

¹⁹Since $r_i^2 = (2\lambda_L)^2 \sim 1/n_{cp}$, the universality of Δ is a necessary condition that the whirls, i.e., ordered Cooper pairs, fill the entire volume of the sample in the MS at any change of n_{cp} (occurring when T changes) regardless of the specific material of the sample.

²⁰ λ_{eff} is such a depth over which the flux of the penetrating field is the same as the flux of the real field and the flux density B is constant and equal to B_{ext} .

Fig. 7 Schematics of the micro-whirl structure in the transverse cross section of type-I (A) and type-II (B) superconductors. In (A) $r_i < R_\perp$ or $\kappa < 1$; in (B) $r_i > R_\perp$ or $\kappa > 1$. The induced currents (all are in phase with each other) are designated by arrows. Areas filled with Cooper pairs are colored in pink; the cross-sectional areas of the induced currents are colored in blue. $R_\perp$ is the rms projection of the pairs radius R_0 onto the plane perpendicular to $\mathbf{H}$; r_i is the rms radius of the induced motion of the paired electrons. Boundaries of all cylinders are diffuse (unsharp), the cylinders overlap without leaving voids. The field $\mathbf{H}$ is directed toward the reader. After Kozhevnikov V (2021) *Journal of Superconductivity and Novel Magnetism* 34: 1979; reprinted with permission from Springer Nature.

Indeed, we have seen that entropy of the ensemble of Cooper pairs S_{cp} is zero. Therefore, according to the Third law (Nernst's theorem), the temperature of the ensemble of Cooper pairs T_{cp} is zero as well, regardless on the sample temperature T . Hence, all results obtained in this section hold in the whole temperature range of the existence of Cooper pairs. In other words, the paired electrons are in the ground state in the entire temperature and field range of the S state.

However, $T_{cp} = 0$ does not mean that the sample temperature has no effect on the properties of paired electrons, since otherwise T_c would be infinite. The sample temperature affects the lattice polarization responsible for the electron pairing. Correspondingly, it changes $n_s (= 2n_{cp})$, as shown in the two-fluid model. Therefore, the change of T leads to the change of λ_L and, correspondingly, to the change of r_i , the rms radius of the field-induced motion of electrons in the pairs. On the other hand, r_i is proportional to R_0 with the proportionality coefficient κ (more strictly $\sqrt{2/3}\kappa$) determined by the superconducting material. In its turn, κ does not depend on T due to the constancy of $T_{cp} (= 0)$.

Flux quantization

Let us consider a closed macroscopic loop l located inside a sample in the MS away from its surface. For simplicity, take a cylindrical sample and the loop lying in the transverse plane as shown in Fig. 8A. Now, calculate the circulation of the linear momentum $\tilde{\mathbf{p}}_{cp}$ over this loop.

Moving along the loop, we will pass through lots of pairs, so we should consider the average momentum $\langle \tilde{\mathbf{p}}_{cp} \rangle$ and the average quantum number $\langle n \rangle$. Since all Cooper pairs are in identical conditions $\langle n \rangle = n$. Therefore, the Bohr-Sommerfeld quantization condition for this case is

$$\oint_l \langle \tilde{\mathbf{p}}_{cp} \rangle \cdot d\mathbf{l} = nh, \quad (27)$$

where l is the loop length.

Now, open $\langle \tilde{\mathbf{p}}_{cp} \rangle$ and take into account that in the MS $n = 0$. Then, Eq. (27) becomes

Fig. 8 Cross section of solid (A) and hollow (B) cylindrical samples in a field $\mathbf{H}_0$ parallel to the long axis of the samples. l is a loop lying away from the wall(s) of the cylinders.

$$\oint_l \langle \tilde{\mathbf{p}}_{cp} \rangle \cdot d\mathbf{l} = \oint_l \langle m\mathbf{v}_{i1} \rangle \cdot d\mathbf{l} + \oint_l \langle m\mathbf{v}_{i2} \rangle \cdot d\mathbf{l} + \frac{2e}{c} \oint_l \langle \mathbf{A} \rangle \cdot d\mathbf{l} = 0. \quad (28)$$

The first two integrals are zero due to mutual compensation of the induced kinetic linear momentums of electrons in neighboring pairs, similar as it takes place in the regular diamagnetics.

Now, what is $\langle \mathbf{A} \rangle$, the average of the vector potential of the intensity $\mathbf{H}$? To answer, we apply Stokes' theorem; then Eq. (28) is rewritten as

$$\frac{2e}{c} \oint_l \langle \mathbf{A} \rangle \cdot d\mathbf{l} = \frac{2e}{c} \int_{F_l} (\nabla \times \langle \mathbf{A} \rangle) \cdot d\mathbf{f} = 0 \quad (29)$$

where F_l is the area of a surface bounded by the loop l and $d\mathbf{f}$ is a vector element of this surface.

From Eq. (29) we see that the integral over the area F_l is the flux of a vector $[\nabla \times \langle \mathbf{A} \rangle]$ and this flux equals zero. Therefore, since $\nabla \times \mathbf{A} \equiv \mathbf{H} \neq 0$, $\langle \mathbf{A} \rangle \neq \mathbf{A}$.

On the other hand, inside our sample the induction $\mathbf{B}$ and therefore its flux is zero (Eq. (39)). Therefore, Eq. (29) suggests that $\langle \mathbf{A} \rangle$ is the vector potential of the magnetic flux density (induction) $\mathbf{A}_B$ defined as $\mathbf{B} = \nabla \times \mathbf{A}_B$. In other words, the vector potential of the flux density $\mathbf{A}_B$ is a macroscopic average of the vector potential $\mathbf{A}$ determining the field induced microscopic currents $\mathbf{j}_i$. This is an exact match with the classical definition of $\mathbf{A}_B$ as a macroscopic mean of the vector potentials caused by the microscopic currents. So, putting $\langle \mathbf{A} \rangle = \mathbf{A}_B$, we rewrite Eq. (29) as

$$\frac{2e}{c} \int_{F_l} (\nabla \times \langle \mathbf{A} \rangle) \cdot d\mathbf{f} = \frac{2e}{c} \int_{F_l} \mathbf{B} \cdot d\mathbf{f} = \frac{2e}{c} \Phi = 0, \quad (30)$$

where Φ is the magnetic flux through the area F_l .

Now, take a hollow (tube-like) thick-wall long cylinder shown in Fig. 8B, apply the field $H_0 (< H_{c1})$ parallel to its longitudinal axis and cool the cylinder below T_c . The loop l encircles the opening of the cylinder and lies inside the wall far (compare to λ) from the inner and outer cylinder surfaces. The induction inside the wall is zero, implying that, as in Eq. (28), $\langle m\mathbf{v}_i \rangle = 0$. On the other hand, the flux Φ inside the hollow cylinder is frozen and therefore it is not zero. Then Eq. (27) yields

$$\oint_l \langle \tilde{\mathbf{p}}_{cp} \rangle \cdot d\mathbf{l} = \frac{2e}{c} \oint_l \langle \mathbf{A} \rangle \cdot d\mathbf{l} = \frac{2e}{c} \int_{F_l} \nabla \times \langle \mathbf{A} \rangle \cdot d\mathbf{f} = \frac{2e}{c} \int_{F_l} \mathbf{B} \cdot d\mathbf{f} = \frac{2e}{c} \Phi = nh. \quad (31)$$

Hence, the magnetic flux passing through the opening (plus surrounding it penetration area) in a multiply connected superconductor is

$$\Phi = \frac{c}{2e} nh. \quad (32)$$

This is the famous London's flux quantization but for the paired electrons. Hence, the origin of the superconducting flux quantization is the Bohr-Sommerfeld quantization condition, which also justifies existence of the field induced persistent currents in the MS.

Eq. (32) implies that the flux quantum and therefore the flux passing through each so-called Abrikosov vortex in type-II superconductors in the mixed state is

$$\Phi_0 = \frac{c}{2e} h = \frac{\pi c \hbar}{e}. \quad (33)$$

As well known, the flux quantization Eq. (32) and the single flux quantum in the Abrikosov vortices Eq. (33) are in full agreement with experiment.

Thus, inside the S phase the vector potential $\mathbf{A}_B = \langle \mathbf{A} \rangle$, where $\mathbf{A}$ is the vector potential of the field $\mathbf{H}$. Now, what is the value of $\mathbf{A}_B$ inside the sample in the MS?

In the plane perpendicular to $\mathbf{H}$ we have uniformly distributed identical induced circular currents, i.e. in-plane currents with the same magnitude j_{cp} and the same rms radius r_i circulating clockwise relative to $\mathbf{H}$. Therefore, exactly as it takes place in regular diamagnetics, equal amount of electricity flows in opposite directions throughout an out-of-plane cross section of an arbitrary chosen volume element dV . Hence, an average current density $\langle \mathbf{j} \rangle = en_s \langle \mathbf{v}_i \rangle$ is zero in any volume element of the sample interior or inside the S phase. So, taking into account Eq. (9), we write

$$\mathbf{A}_B \equiv \langle \mathbf{A} \rangle = \langle \mathbf{v}_i \rangle = \langle \mathbf{j} \rangle = 0. \quad (34)$$

Thus, inside the sample in the MS, or in general inside the S phase, in spite of non-zero $\mathbf{H}$, an average of its vector potential $\langle \mathbf{A} \rangle$, as well as the average induced velocity $\langle \mathbf{v}_i \rangle$, and the average induced current $\langle \mathbf{j} \rangle$ are all equal zero. Out of these three equalities the last one [$\langle \mathbf{j} \rangle = 0$] is the most important: it shows that all currents in the S phase are mutually compensated, as required by the Law of the time reversal symmetry.

Total current

As we have seen, the equilibrium magnetic properties of superconductors are qualitatively similar to the properties of conventional diamagnetics. In both cases these properties are due to magnetization arising from precession of the microscopic magnetic moments caused by the orbital motion of electrons bound either in atoms (conventional diamagnetics) or in Cooper pairs (superconductors). A colossal quantitative difference in the magnetic susceptibilities in these materials (up to 5 orders of magnitude!) is due to the differences in the size of the orbits and correspondingly in the radii of the induced microscopic currents of the bound electrons.

However, there is also an important qualitative difference in these induced currents. Namely, in conventional diamagnetics the orbiting electrons are bound in motionless atoms (fixed in the crystal lattice), while in superconductors - in movable Cooper pairs. The pairs mobility allows them to compose the whirl structure with zero entropy. On the other hand, since the pairs have electric charge, they can form an electric current, referred to as the total current. It includes the transport current and the field-induced current encircling the openings in multiply connected bodies. In the latter case, as was for the first time observed by [Deaver and Fairbank \(1961\)](#), the total current is quantized due to the flux quantization.

The total current in superconductors plays a role similar to that of the transport current in conventional metals, where it is executed by conduction electrons. The latter obey Fermi-Dirac statistics and their energy equals the Fermi energy E_F . This implies that the carriers of the transport current in normal metals, or in the N phase of superconductors, are “very hot”: their temperature, the temperature of the ensemble of conduction electrons, equals the Fermi temperature $T_F = E_F/k_B \sim 10^4$ K (k_B is the Boltzmann constant), i.e., it is about the same as the sun surface temperature.

In striking contrast, the charge carriers (Cooper pairs) of the total current in the S phase are “deadly cold.” Since their spins are zero, the pairs obey Bose-Einstein statistics and, since the temperature of the ensemble of the paired electrons T_{cp} is zero, they form the Bose-Einstein condensate (BEC). This (zero temperature) leads to the disappearance of the thermoelectric effects, as observed in experiments. The amazing transformation of the “very hot” single electrons to the “zero-temperature” electron pairs can be compared with the fact known from the relativity theory: two flying apart massless photons form a massive pair located in their center of mass.

Therefore, the total current in superconductors represents the transport current in BEC, known on the properties of superfluid helium. Correspondingly, the total current set in a closed superconducting circuit continues running without energy dissipation provided speed of the charge carriers (density of the total current) is lesser of a definite critical value ([Landau, 1941](#); [Feynman, 1955](#)).

Thus, in the MW model the electromagnetic properties of superconductors caused by the total current²¹ resemble the properties of hypothetical perfect conductors.

The hell-mark of the perfect conductors is irreversibly of the sample magnetic moment induced by the changing applied magnetic field; its direction is determined by the Lenz law whereas the magnetic moment caused by magnetization is always diamagnetic. On this reason the multiply connected bodies can never be in thermodynamic equilibrium and therefore neither the principal of the free energy minimum nor the time reversal symmetry can be applied to them.

However, it should be stressed that even in the presence of the total current, magnetic properties of superconductors in the MW model are different from those of the perfect conductors. Since the total current is accompanied by its own magnetic field, it represents a combination of the whirl and translational motion of the paired electrons regardless of the presence or absence of the applied field. This explains the observation reported by [Meissner and Ochsenfeld](#) in their fundamental paper of 1933 ([Meissner and Ochsenfeld, 1933](#)): “When the parallel superconductors are connected end-to-end in series and an external current is connected to flow through them above the critical temperature the magnetic field between the superconductors is increased below the transition temperature the external current being unchanged.”

Conclusion

In this chapter we presented the basics of the micro-whirls model of superconductivity and a description of main electrodynamic properties as it follows from the model. It is important to underline, that the “big zeroes” of superconductivity listed in the abstract, as well as the zero generalized linear momentum (modified London’s rigidity), the zero average vector potential and the zero average current in the sample bulk, all rise from a single root: quantization of the angular momentum of electrons combined into Cooper pairs. It will not be redundant to note that the fact of zero temperature of Cooper pairs regardless of the sample temperature means that there is no fundamental limit in the critical temperature of superconductors, as it is really observed after the discovery of high-temperature superconductors by [Bednorz and Müller](#) in 1986 ([Bednorz and Müller, 1986](#)).

²¹We are talking about the dc total current. Consideration of the ac current must include contribution of the unpaired electrons, which is significant at frequencies $\gtrsim 10^3$ MHz.

Acknowledgments

The author is deeply grateful to Prof. Vladimir Kresin and Prof. Orest Simko for valuable comments after reading the manuscript. After the submission of this chapter, tragic news came: on July 28, Professor Kresin passed away. Vladimir Kresin was a brilliant physicist and real gentleman. This chapter is dedicated to his blessed memory.

Abstract

Since the discovery by Kamerlingh Onnes in 1911 superconductivity has remained an important phenomenon in solid state physics with continuing discoveries. The explanation of the superconductivity phenomenon was given by the most elegant BCS theory of Bardeen, Cooper, and Schrieffer in 1957. The formation of Cooper pairs results from an effective attractive phonon-mediated interaction between two electrons with opposite spin near the Fermi surface. The BCS theory provided justification to the successful phenomenological Ginzburg–Landau theory from 1950. We discuss the BCS theory, Josephson tunneling of Cooper pairs between tunnel junctions, and the McMillan equation for the superconducting transition temperature and use this for its pressure dependence and for superconductivity in amorphous metals. We also discuss the Eliashberg theory treating electrons and phonons in superconductors on the same footing. Furthermore, we also discuss the high transition temperature (cuprate) superconductors for which the Cooper pair glue is still debated and for which the repulsive coupling yields an order parameter of d-symmetry. Interesting behavior of various superconducting nanostructures (e.g., system of quantum dots) is discussed. This is a corrected and extended version of the chapter (Bennemann, 2005).

Key points

- The BCS theory provided the most elegant microscopic explanation of the superconductivity phenomenon.
- Formation of Cooper pairs results from an effective attractive phonon-mediated interaction between two electrons with opposite spin near the Fermi surface.
- The BCS theory provided a justification to the successful phenomenological Ginzburg–Landau theory.
- Josephson tunneling of Cooper pairs between tunnel junctions is discussed.
- The McMillan equation for the superconducting transition temperature is used for description of its pressure dependence and for explaining superconductivity in amorphous metals.
- The Eliashberg theory treats electrons and phonons in superconductors on the same footing.
- In the high transition temperature (cuprate) superconductors, the Cooper pair glue is still debated and the repulsive coupling yields a d-symmetry of the order parameter.
- Behavior of various superconducting nanostructures (e.g., system of quantum dots) is discussed.

Introduction

For many years, superconductivity has remained one of the most interesting phenomena in physics. After its discovery by Kamerlingh Onnes in 1911, many superconductors have been found, see Fig. 1. The discovery of MgB_2 as a superconductor with a transition temperature $T_c = 39$ K suggests that further surprises can be expected in the future. The basic interdependence of superconductivity and lattice structure still needs to be understood. Fig. 2 shows the transition temperature of some interesting metals.

Some of the cornerstones in the history of superconductivity were the observation of (1) a vanishing electrical DC resistivity $\rho(T)$ at T_c , (2) the magnetic behavior exhibiting type-I superconductors expelling magnetic flux (Meissner–Ochsenfeld), and type-II superconductors where quantized magnetic flux can penetrate in filaments, (3) the isotope effect, $T_c \propto M^{-\alpha}$, for example, $\alpha \approx 0.5$ for Hg, suggesting that the electron–phonon coupling might be responsible for superconductivity, and (4) Josephson tunneling with an electronic current $j = j_0 + j_1 \sin[\Delta\phi - (2eV_{21}/\hbar)t]$, where $\Delta\phi$ is the phase difference and V_{21} the voltage between two superconductors 1 and 2. There are many additional interesting observations including the occurrence of a gap in the electronic density of states (DOS),

Fig. 1 The occurrence of superconductivity in the periodic table is illustrated. As the history of superconductivity shows, alloys and compounds of the elements play an important role. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

Fig. 2 History of the transition temperature T_c for the first 70 years following the discovery of superconductivity in 1911. The A-15 compounds were of particular interest in the search for higher T_c superconductors. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

gapless superconductors, and the interdependence of atomic structure and T_c , seen in particular in layered structures, and granular superconductors.

Most important theories developed for a physical understanding of the superconductivity phenomena were: (1) the London theory in 1935 explaining the Meissner–Ochsenfeld effect by using for the superconducting current driven by the vector potential the expression $\mathbf{j}_s = -(c/4\pi\lambda_L^2)\mathbf{A}$, with the penetration depth, $\lambda_L = (mc^2/4\pi e^2 n_s)^{1/2}$, where n_s is the superfluid density (Abrikosov et al., 1963). (2) the Ginzburg–Landau theory in 1950, which extended the London theory by writing the free energy in terms of an order parameter $\psi(\mathbf{r}, t) = |\psi|e^{i\varphi(\mathbf{r})}$ as,

$$F = F_0 + \int d^3r \left\{ a|\psi|^2 + \frac{b}{2}|\psi|^4 + \frac{\hbar^2}{2m^*} \left| \left(\nabla - i \frac{e^*}{\hbar c} \mathbf{A} \right) \psi \right|^2 + \frac{\hbar^2}{8\pi} \right\}, \quad (1)$$

yielding the current via minimization with respect to ψ (or ψ^*):

$$\mathbf{j} = -i \frac{\hbar e^*}{2m^*} (\psi^* \nabla \psi - \psi \nabla \psi^*) - \frac{e^{*2}}{m^* c} |\psi|^2 \mathbf{A}. \quad (2)$$

In 1957, the Bardeen–Cooper–Schrieffer (BCS) theory (Bardeen et al., 1957) [see also Parks (1969) and Schrieffer (1964)] derived superconductivity from an electronic Hamiltonian $H = H_0 + H_{\text{eph}}$, where H_{eph} describes the electron–phonon interaction. It is to be noted that Eq. (2) immediately yields the Meissner effect, by assuming that the superconducting wave function is rigid and is not

affected by an electromagnetic field (thus, the first term in Eq. (2) is zero), and for $\psi = |\psi|e^{i\phi(r)}$ ($\psi\psi^* \sim n_s$ and ϕ are conjugate variables). The Josephson tunnel current between two superconductors 1 and 2 (with phase and voltage difference $\Delta\phi$, ΔV) is given by

$$j_J = j_0 \sin\left(\Delta\phi - \frac{e^*}{\hbar} \Delta V t\right) \quad (3)$$

Here,

$$\Delta\phi = \varphi_1 - \varphi_2 + \frac{2\pi}{\phi_0} \int_1^2 d\mathbf{l} \cdot \mathbf{A}$$

$$j_0 = \frac{e^* \hbar}{m^* d} |\psi|^2, \quad (m^* = 2m, \quad e^* = 2e)$$

and d is a parameter referring to the tunnel junction, $\phi_0 = hc/2e$. Assuming the single-valuedness of ψ , one obtains the quantization of flux trapped (in a filament) in a superconductor (see gauge transformation ψ):

$$\phi = n\phi_0, \quad n = 0, \pm 1, \dots \quad (4)$$

These are remarkable general results that hold for different possible mechanisms causing condensation of a Fermi liquid into a superconducting state.

The BCS theory is one of the most elegant theories in physics; it effectively explains superconductivity resulting from Cooper pairs ($\mathbf{k}\uparrow, -\mathbf{k}\downarrow$) for electrons with opposite spin and momentum $\mathbf{k}$ at the Fermi surface. As illustrated in Fig. 3, the exchange of virtual phonons yields an attractive interaction and thus a singlet Cooper pairing. This pairing causes a gap in the single-electron DOS, reflecting the binding energy of the Cooper pairs, $\Delta = \Delta(T, \hbar, \dots)$. The theory correctly predicts the behavior and some other thermodynamical and electrodynamical quantities.

Following the BCS theory, the quantum field theory using the Green's function method, in particular by Gor'kov et al., gave the theory of superconductivity a very elegant form. In general, for phase transitions (ferromagnetism, etc.), the superconducting state cannot be obtained from the normal state by using the perturbation theory. That the electron-phonon interaction described in second-quantization notation by

$$H_{\text{eph}} = \sum_{\mathbf{k}, \mathbf{k}', \lambda} g_{\mathbf{k}\mathbf{k}'\lambda} c_{\mathbf{k}'}^{\dagger} c_{\mathbf{k}} (d_{\lambda}(\mathbf{q}) + d_{\lambda}^{\dagger}(-\mathbf{q})) + \dots \quad (5)$$

is responsible for superconductivity was suggested earlier by Fröhlich and others and explains, for example, the isotope effect. Here $c_{\mathbf{k}}$ and $c_{\mathbf{k}}^{\dagger}$ represent the electron annihilation and creation operators, while $d_{\lambda}(\mathbf{q})$ and $d_{\lambda}^{\dagger}(\mathbf{q})$ are the corresponding annihilation and creation operators for phonons of momenta $\mathbf{q} = \mathbf{k}' - \mathbf{k}$. The electron-phonon coupling constant is given by

$$g_{\mathbf{k}\mathbf{k}'\lambda} = \sum_{i,\alpha} \left(\frac{\hbar N_{\alpha}}{2\omega_{\mathbf{q}\lambda} M_{\alpha}} \right) \langle \mathbf{k}' | \nabla_i U_{i\alpha} | \mathbf{k} \rangle \mathcal{E}_{\lambda}(\alpha) e^{i\mathbf{q}\cdot\mathbf{r}_{\alpha}^0} \quad (6)$$

where $U_{i\alpha}$ is the potential of the ion i, α and $\mathcal{E}_{\mathbf{q}\lambda}$ are the lattice polarization vectors. Since, as illustrated in Fig. 3, emission and absorption of phonons by electrons at the Fermi surface can lead to an effective attractive interaction, it seemed possible that Cooper pairing ($\mathbf{k}\uparrow, -\mathbf{k}\downarrow$) occurs for electrons within an energy shell of $2\omega_D$, where ω_D is the Debye frequency. On general grounds, one expects, for an attractive potential with a range of the order of the interatomic distance ($a \sim p_F^{-1}$), due to the Pauli principle, singlet pairing and pairing of $\mathbf{k}$ and $-\mathbf{k}$ electrons to avoid kinetic energy of the Cooper pairs and thus to obtain maximal condensation energy. To avoid the destructive repulsive electron-electron interaction, the pairing results from a retarded potential.

Fig. 3 Illustration of the interaction between electrons with $\mathbf{k}_1$ and $\mathbf{k}_2$ via exchange of a phonon with polarization λ , wave vector $\mathbf{q}$ and energy $\omega_{\mathbf{q}\lambda}$; $\omega_{\mathbf{q}\lambda} \simeq \varepsilon_{\mathbf{k}_1-\mathbf{q}} - \varepsilon_{\mathbf{k}_1}$; then an attractive effective electron-electron interaction $\tilde{g}^2 D < 0$ results, if $\omega < \omega_{\mathbf{q}\lambda}$, $\tilde{g} = g\Gamma$, where Γ denotes many-body corrections to the electron-phonon coupling. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

The electron $k\uparrow$ polarizes the lattice for a time of the order of $t \sim \omega_D^{-1}$, which is slower than the electron motion, and then the other electron $-k\downarrow$, arriving at the polarized lattice within that time might feel an effective attractive electron–electron interaction due to over-screening. The resultant binding energy 2Δ causes a correlation and coherence length of the order of $\xi \sim v_F/2\Delta$. It is to be noted that Coulomb fields are screened at a distance of the order of the interatomic distance. This analysis and the study by Cooper, showing that for electrons at the Fermi surface the pair wave function $\psi = \sum_{k \sim k_F} a_k e^{ik \cdot \mathbf{r}}, \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$ lowers the energy $((H_0 + V)\psi = E\psi$ and $V < 0$), gave a more definite clue that the Cooper pairing of the electrons within an energy shell of the order of $2\hbar\omega_D$ causes superconductivity.

Cooper pairing is the essence of the electronic BCS theory, also for the novel superconductivity of the cuprates like YBCO and HgBCCO, which gives the microscopic justification of the phenomenological Ginzburg–Landau theory. Its formulation was achieved with the help of quantum field-theoretical methods (Tinkham, 1975).

BCS theory

The BCS theory begins by using the Hamiltonian

$$H = \sum_{k,\sigma} \xi_k n_{k\sigma} + \sum_{k,k'} V_{kk'} a_{k\uparrow}^\dagger a_{-k\downarrow}^\dagger a_{-k'\downarrow} a_{k'\uparrow} \quad (7)$$

with excitation energies $\xi_k = \varepsilon_k - \mu$ for electrons near the Fermi energy (μ is the chemical potential) and the effective interaction $V_{kk'}$ between electrons with wave vectors $\mathbf{k}$ and $-\mathbf{k}$, and spin $\uparrow$ and $\downarrow$. Note that the remaining interactions between the electrons are assumed to be included in the energies ξ_k . $a_{k\sigma}^\dagger$ and $a_{k\sigma}$ are the usual creation and annihilation operators for fermions with momentum $\mathbf{k}$ and spin σ , and $n_{k\sigma}$ is the particle number occupation operator. The BCS theory uses the wave function,

$$|\psi\rangle = \prod_k (u_k + v_k a_{k\uparrow}^\dagger a_{-k\downarrow}^\dagger) |\psi_0\rangle, \quad |u_k|^2 + |v_k|^2 = 1, \quad (8)$$

to calculate the free energy. The ground state is $|\psi_0\rangle$. $|v_k|^2$ gives the probability of a pair $(k\uparrow, -k\downarrow)$. The diagonalization of H is most elegantly achieved by the Bogoliubov and Valatin canonical transformations

$$b_{-k+} = u_k a_{-k\downarrow} + v_k a_{k\uparrow}^\dagger, \quad b_{k-} = u_k a_{k\uparrow} - v_k a_{-k\downarrow}^\dagger, \quad u_k^2 + v_k^2 = 1, \quad (9)$$

which introduce new fermion operators $b_{k\sigma}$ and $b_{k\sigma}^\dagger$. Due to isotropy, the coefficients u_k and v_k depend only on k and can be chosen to be real and such that, for a given entropy, the electronic energy E is minimal. Then one gets straightforwardly (with $V_{kk'} = -g/V$),

$$E = \sum_k \xi_k \left[2v_k^2 + (u_k^2 - v_k^2) \sum_{\sigma=\pm} N_{k\sigma} \right] - \frac{g}{V} \left[\sum_k u_k v_k \left(1 - \sum_{\sigma=\pm} N_{k\sigma} \right) \right]^2, \quad (10)$$

where $N_{k\sigma} = b_{k\sigma}^\dagger b_{k\sigma}$ and, from $\partial E / \partial u_k$, the result,

$$2\xi_k u_k v_k = \Delta_k (u_k^2 - v_k^2). \quad (11)$$

Here, using $u_k^2 + v_k^2 = 1$ and Eq. (9), the order parameter $(\Delta_k \propto \langle a_{-k\downarrow} a_{k\uparrow} \rangle)$,

$$\Delta_k = \frac{g}{V} \sum_k u_k v_k \left(1 - \sum_{\sigma=\pm} N_{k\sigma} \right) \quad (12)$$

has been introduced. The order parameter can be expressed as

$$\Delta_k = \frac{g}{V} \sum_{k'} \frac{\Delta_{k'}}{2\xi_{k'}} \tanh\left(\frac{\xi_{k'}}{2k_B T}\right) \quad (13)$$

$$\xi_k = \sqrt{\xi_k^2 + \Delta_k^2}.$$

It is of interest to note that Eq. (13) has solutions not only for attractive interaction (with $g > 0$) but possibly also for repulsive ones with $g < 0$. Then the k -dependence of Δ_k is important.

The new quasiparticle energies are $\mathcal{E}_k = (dE/dN_k)_{u_k, v_k} = \sqrt{\xi_k^2 + \Delta_k^2}$. Their distribution function is $N_k = (e^{\mathcal{E}_k/k_B T} + 1)^{-1}$. These quasiparticles contribute to the energy the term $\sum_{k,\sigma} \mathcal{E}_k N_{k\sigma}$. It is to be noted that $2\Delta_k$ is the binding energy of the correlated electrons. Thus, the coherence length $\xi = \hbar v_F / 2\Delta$ yields the correlation distance, for most conventional superconductors, a much larger value than the interatomic distance $\hbar/p_F$.

Note that for an isotopic gap $\Delta_k = \Delta$ one gets

$$1 = \frac{g}{V} \sum_k \frac{1}{2\sqrt{\xi_k^2 + \Delta^2}} \tanh\left(\frac{\sqrt{\xi_k^2 + \Delta^2}}{2k_B T}\right). \quad (14)$$

and from this, for $\Delta(T)$, the expression

$$\Delta(T) = 3.2k_B T_c \left(1 - \frac{T}{T_c}\right)^{1/2}. \quad (15)$$

The superconducting transition temperature T_c follows from $\Delta(T_c)$. Thus, $\left(\sum_k \rightarrow \int_{-\omega_D}^{\omega_D} d\varepsilon\right)$,

$$T_c \simeq 1.14 \hbar \omega_D e^{-1/(N(0)g)} \propto M^{-1} \quad (16)$$

$$\frac{2\Delta(0)}{k_B T_c} = 3.52.$$

As shown by [McMillan \(1968\)](#), [Bennemann and Garland \(1972\)](#), and others, Eq. (16) needs to be improved to calculate realistic T_c values for simple metals, transition metals, A-15 compounds, alloys, etc., and to understand the interdependence of superconductivity and atomic structure better. Taking into account more details of the electron–phonon coupling, the phonon spectrum, the retardation of the pairing potential, and the remaining repulsive electron–electron interaction ($\propto \mu^*$, pseudo-Coulomb potential), one gets the McMillan equation ([McMillan, 1968](#)):

$$T_c \simeq \frac{\omega_D}{1.45} \exp\left[-\frac{1.04(1+\lambda)}{\lambda - \mu^*(1+0.62\lambda)}\right] \quad (17)$$

$$\lambda = 2 \int_0^\infty d\omega \frac{\alpha^2(\omega)F(\omega)}{\omega}.$$

Here, the effective coupling constant λ depends on the DOS, $N(0)$. First, $\lambda \propto N(0)$, then λ saturates and decreases again as $N(0)$ increases such as in transition metals. Note that $\lambda = (m^*/m) - 1$. Typically $\mu^* \approx 0.1$, but μ^* may also change strongly near magnetic instabilities.

The DOS for the quasiparticles is given by

$$N_s(\varepsilon) = N_n(\varepsilon) \frac{\varepsilon}{\sqrt{\varepsilon^2 - \Delta^2}}. \quad (18)$$

This follows from the one-to-one correspondence of old and new quasiparticles, $N_s(\varepsilon)d\varepsilon = N_n(\xi)d\xi$. For the thermodynamic potential Ω , which is the appropriate function for a system with given μ , all thermodynamic properties can be calculated using the formulas,

$$\left.\frac{\partial \Omega}{\partial g}\right|_{T,V,\mu} = -V \frac{\Delta^2}{g^2} \quad (19)$$

$$\Omega_s - \Omega_n = \int_0^\Delta d\Delta' \Delta'^2 \frac{d(1/g)}{d\Delta'}$$

This gives, in particular at T_c , the specific heat ([Fig. 4](#)),

$$c_s - c_n \simeq \frac{4mp_F}{7\zeta(3)\hbar^3} T_c, \quad c_s(T) \propto e^{-\Delta_0/k_B T}, \quad (20)$$

where $\zeta(x)$ is the Riemann–Zeta function, $V = 1$. To obtain the behavior in electromagnetic fields, one uses the recipe $\mathbf{p} \rightarrow \mathbf{p} - (e/c)\mathbf{A}$, $\mathbf{p} \rightarrow -i\hbar\nabla$, where $\mathbf{A}$ denotes the vector potential ($\mathbf{A} = \sum_q \mathbf{a}_q e^{iq\cdot\mathbf{r}}$). This yields the coupling,

$$H_{\text{int}} = i \frac{e\hbar}{2mc} \sum_k (\mathbf{v}_k \cdot \mathbf{A} + \mathbf{A} \cdot \mathbf{v}_k) \quad (21)$$

$$= - \frac{e\hbar}{mc} \sum_{k,q} \mathbf{k} \cdot \mathbf{a}_q c_{k+q,\sigma}^\dagger c_{k\sigma}.$$

Here, the spin is unchanged since $\mathbf{A}$ couples dominantly to the orbital motion of pairing electrons. (Note that $\mathbf{q} \cdot \mathbf{a} = 0$ for transversal fields.) Thus, one obtains, as in the Ginzburg–Landau theory for the electric current due to $\mathbf{A}$ ($\mathbf{j} = env$) for Cooper pairs ($m \rightarrow 2m$, $e \rightarrow 2e$),

$$\mathbf{j} = - \frac{ne^2}{mc} \mathbf{A} + \mathbf{j}_2, \quad (22)$$

where the paramagnetic current is $\mathbf{j}_2 = e\hbar/m \sum_{k,q} \mathbf{k} a_{k-q}^\dagger a_k$, which would vanish if the superconducting wave function ψ is rigid, that is, not affected by $\mathbf{A}$.

It is to be noted that, since n_s is the density of Cooper pairs, the first term gives the famous London equation

Fig. 4 Illustration of (A) the gap Δ in the elementary excitation spectrum, (B) the jump $(C_s/C_n)T_c = 2.43$ in the specific heat, and (C) the electronic DOS. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

$$\begin{aligned} j_1 &= -\frac{n_s e^2}{mc} A = -\frac{c}{4\pi\lambda^2} A \\ \lambda^2 &= \frac{mc^2}{4\pi e^2 n_s}. \end{aligned} \quad (23)$$

Hence, by determining the penetration depth λ of an external magnetic field $\mathbf{h}$ into a superconductor, one may calculate the superfluid density n_s , an important quantity reflecting whether all electrons at the Fermi surface pair. Evidently, if $\xi > \lambda$, Eq. (22) gives the Meissner effect. Using the response theory,

$$\mathbf{j}_q = -\frac{c}{4\pi} K_q \mathbf{a}_q, \quad (24)$$

where $K_q = \lambda^{-2}(1 + \lambda^2 K_q')$ and K_q' is calculated within the BCS theory.

The two characteristic length scales ξ and λ suggest that there exist two types of superconductors characterized by $\kappa = \lambda/\xi$. As shown by Abrikosov, they correspond to types I ($\kappa < 1/\sqrt{2}$) and II ($\kappa > 1/\sqrt{2}$). Superconductors of type I repel an external magnetic field, which however may penetrate via an array of quantized flux filaments into type-II ones. For these, one expects vortex lines with $\Delta \simeq 0$ around them. The superconductor compromises both effects in order to profit from the Cooper-pair condensation energy and the magnetic field energy. It is to be noted that the formation of a vortex costs an energy of the order $(\xi^2 h^2/8\pi)$ due to a variation of $\Delta(r)$ or the wave function ψ , and reduces the (diamagnetic) field energy by about $(\lambda h^2/8\pi)$. Fig. 5 characterizes the behavior of superconductors in an external magnetic field. From the general formula for the free energy,

$$F_s = F_n - \frac{h^2}{8\pi}, \quad (25)$$

assuming no field penetration into the superconductor, one gets a critical magnetic field, H_{c1} below which a pure Meissner superconductor is present. Above H_{c1} , the magnetic flux ϕ may penetrate until $H_{c1} = \phi/\pi\xi^2$ (ϕ = flux of area $\pi\xi^2$). As already noted, the flux ϕ is quantized due to the macroscopic phase of the superconductor as a whole. Note that for fields h such that $H_{c1} < h < H_{c2}$ one gets a mixed state, with $H_{c2} = \sqrt{2}\kappa H_{c1}$. Surfaces may favor Cooper-pair condensation. Then there exists another critical field H_{c3} above which superconductivity at the surface is destroyed ($H_{c3} \simeq 1.7H_{c2}$).

Obviously, strong magnetic fields may also affect Cooper pairing by destroying the singlet state. This is of relevance for the interdependence of superconductivity and magnetism in antiferromagnets or ferromagnets. As a result of internal molecular fields acting on the electron spins, one may get a spatially inhomogeneous superconducting state, $\Delta = \Delta(\mathbf{k}, \mathbf{r})$, and then again a compromise to profit from both Cooper pairing energy and magnetic energy.

The spin-orbit coupling and scattering by local spins (paramagnetic impurities) also affect the singlet pairing. Scattering by paramagnetic impurities with spins via exchange coupling (J), $H_{\text{ex}} = -J\sum_i \mathbf{S}_i \cdot \boldsymbol{\sigma}$, will, of course, weaken the singlet Cooper pairing. The interesting analysis by Abrikosov and Gor'kov yields

Fig. 5 (A) Meissner effect for type-I superconductors where, below the superconducting transition temperature T_c , the magnetic flux B is abruptly expelled; (B) Typical behavior of type-II superconductors, where, below H_{c1} , the flux penetrates, and perfect Meissner effect behavior occurs below H_{c1} ; (C) dependence of type-I superconductor on B and j and (D) temperature dependence of critical magnetic fields. At H_{c3} , surface superconductivity disappears, $B = H + 4\pi M$. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

$$\ln\left(\frac{T_c}{T_{c0}}\right) = \psi\left(\frac{1}{2}\right) - \psi\left(\frac{1}{2} + \frac{\hbar}{4\pi\tau T_c}\right), \quad (26)$$

where τ is spin scattering time and $\psi(x) = \Gamma'(x)/\Gamma(x)$ is the digamma function. The discovery of gapless elementary excitations was unexpected. The effects on the singlet superconducting state due to spin-mixing via spin-orbit coupling and spin-flip scattering via exchange interaction are observed through the temperature dependence of the Knight shift $K(T)$, for example, and cause $K > 0$ for $T \rightarrow 0$. Clearly, the spin splitting of the Fermi surface for spin $\uparrow$ and $\downarrow$ electrons also weakens pairing of $\mathbf{k}$ and $-\mathbf{k}$ electrons.

For a better understanding of the phonon and electron dynamics due to H_{eph} , one can use the Hamiltonian $H = H_0 + H_{\text{eph}} + H_{\text{el}}$, where H_0 refers to phonons and electrons in the absence of H_{eph} , and H_{el} to the electron-electron interactions. The dynamic field operators ψ , ψ^+ , and φ (in this context φ represents the phonon field, which is $\propto d + d^+$ introduced earlier) are treated on the same level. This yields renormalizations of both phonon and electron excitations. The physical situation is illustrated in Fig. 6. Then one obtains a frequency-dependent complex superconducting order parameter $\Delta(\omega)$ and, for the DOS (see Fig. 7),

$$N_T(\omega) \sim \text{Re} \frac{\omega}{\sqrt{\omega^2 - \Delta^2(\omega)}}. \quad (27)$$

Using matrix Green's functions, the Nambu notation $\psi_k^+ = \begin{pmatrix} c_{k\uparrow}^+ & c_{-k\downarrow} \end{pmatrix}$, and Matsubara frequencies, one gets for $\mathcal{G}_k(\tau) = -\langle T_\tau \psi_k(\tau) \psi_k^+(0) \rangle$, and similarly for $\mathcal{D}(\mathbf{q}, \tau)$, the Dyson equations shown in Fig. 6 where

$$\mathcal{G} = \begin{pmatrix} G & F \\ F^+ & \tilde{G} \end{pmatrix}, \quad \mathcal{G}_0 = \begin{pmatrix} G_0 & 0 \\ 0 & \tilde{G}_0 \end{pmatrix}, \quad \mathcal{G}_0 = \begin{pmatrix} D & 0 \\ 0 & \tilde{D} \end{pmatrix}$$

One gets (for $D = (i\omega_n Z)^2 - (\epsilon_k + \xi)^2 - \phi^2$, $\omega_n = (2n + 1)\pi T$)

Fig. 6 Illustration of the dynamics of the coupled electron and phonon systems using Feynman diagrams and thermodynamic matrix Green's functions G, D (Eliashberg-type theory (McMillan, 1968)). The graph(==) refers to an additional electron–electron interaction and also to spin excitations (and impurity scattering) ($g = \text{eph.}$, $g_{el} = \text{el-el.}$). From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

Fig. 7 Tunneling DOS with structure due to electron–phonon interaction. Also $\Delta(\omega) = \Delta_1 + i\Delta_2$ is given (ω_1^t : phonon frequency). From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

$$G(\mathbf{k}, i\omega_n) = \frac{i\omega_n + \varepsilon_{\mathbf{k}} + \xi}{D}, \quad F(\mathbf{k}, i\omega_n) = \frac{\phi(\mathbf{k}, i\omega_n)}{D}, \quad (28)$$

for the electron (G) and Cooper pair Green's function (F), respectively. Note that $D = 0$ yields the elementary excitations and $\Delta = \phi/Z$ the order parameter with $Z \simeq 1$. After continuation to the real axis, one obtains

$$\Delta(\omega) = \frac{N(0)}{Z(\omega)} \int_{\Delta_0}^{\omega_c} d\omega' \operatorname{Re} \frac{\Delta(\omega')}{\sqrt{\omega'^2 - \Delta^2}}, \quad (29)$$

with $U_c = V_c/(1/N(0)V_c \ln(\omega_m/\omega_0))$ due to electron–electron interactions, ($\omega_m \sim \varepsilon_F$, ω_0 —cutoff parameter) and (from phonon spectrum $B_z(q, z)$),

$$K_{ph} = \sum_z \int_0^{2k_F} \frac{dgq}{2k_F^2} \int_0^\infty dz B_z(q, z) |g_{qz}|^2 \times \left(\frac{1}{\omega' + \omega + z - i\delta} + \frac{1}{\omega' - \omega + z - i\delta} \right). \quad (30)$$

These equations are the essence of the Eliashberg-type theory (McMillan, 1968) and produce, for a simplified phonon spectrum, the results obtained by Scalapino, Schrieffer, and Wilkins (SSW) (Scalapino et al., 1966) shown in Fig. 7. This analysis is of utmost significance since it shows definitely that for BCS-type superconductors the electron–phonon coupling causes Cooper pairing. Note that phase-coherent Cooper pairs occur at T_c . The phonon frequencies are

$$\omega_q^2 \simeq \left(\omega_q^0\right)^2 + 2\omega_q^0 \frac{|g_q|^2}{V_c(q)} \left[\frac{1}{\varepsilon(q, \omega)} - 1 \right], \quad (31)$$

where $\varepsilon(q, \omega)$ is the dielectric function. Presumably, the Dyson equation illustrated in Fig. 6 also applies if $\mathcal{D}$ is replaced by the Green's function of spin excitations, the dynamical spin susceptibility $\chi(q, \omega)$, or of other modes that possibly cause Cooper pairing. Fig. 6 describes not only singlet but also triplet Cooper pairing such as in He^3 , and also suppression of Cooper pairing due to magnetic interactions; see "Further reading" section. Superconductivity in different materials, for example, isotropic lattices, layered lattice structures, nanostructures, and amorphous metals can be described adequately by taking into account details of the coupling constant $g_{kk'}$ and its renormalization due to vertex corrections (Ward identities) (Table 1).

Novel superconductors

The essence of novel superconductivity in cuprates like LBCO, YBCO, and HgBCCO is the presence of singlet Cooper pairs with d-wave symmetry. Such a symmetry is expected for repulsive coupling g , see the discussion by Manske et al. (2000), as implied by the experimental results for the high superconducting transition temperatures ranging from 100 to 130 K and higher. Manske et al. (2000) have discussed in detail the phase diagram for the high transition temperature cuprates assuming spin fluctuation induced Cooper pairing and including their phase fluctuations expected for underdoped cuprates. Also for positive interaction g , it is argued how the gap equation provides a solution of the d-wave symmetry (Bennemann and Ketterson, 2003, 2014).

Summary and outlook

Both BCS theory and its extension, including dynamical effects yielding the Abrikosov–Gor'kov and Eliashberg theory, explain superconductivity resulting from electron–phonon coupling. It still remains a challenge to calculate T_c from first principles and its dependence on atomic structure, lattice instabilities, and magnetic activity. The results shown in Table 1 were obtained by Garland et al. (1968) using the McMillan equation and assuming phonon softening. A very good agreement with experiment by Buckel and Hilsch (1954) was achieved.

Changes in the atomic structure affect the phonon spectrum and the coupling constant $g_{q\lambda}$ and T_c , Δ , etc., as observed for disordered and amorphous metals. In transition metals and alloys thereof with large $N(0)$, one may attempt to relate T_c to the cohesive energy, since $g \sim \langle \nabla t_{ij} \rangle \sim t$, where t_{ij} is the hopping integral for electrons (see also studies by Labbé et al. (1967)). For a study of pressure-induced superconductivity in narrow band metals (Bennemann and Garland, 1972) both changes in the phonon spectrum and coupling constant g may be important. Similarly, for transition metal alloys A_xB_{1-x} the different bonds (AA, AB, and BB) may play a role in determining $\Delta(x)$ and $T_c(x)$. For this, the BCS theory has been extended by Bennemann and coworkers (see Kerker and Bennemann, 1974), using the coherent-potential approximation. In case of strong anisotropy of the lattice structure as in layered structures, one may expect approximately two coupling constants g_i ($g_i \sim \nabla t_i \cdot e$), different critical fields H_{c2}^{a-b} and H_{c2}^c , and two gaps ($i \simeq \pi, \sigma, a-b$ in plane, $c \perp a-b$)

$$\Delta_i Z_i \simeq \pi T \sum_{l,m} \frac{\lambda_{il} - \mu_{il}^*}{\sqrt{\omega_m^2 + \Delta_l^2(m)}} \Delta_l(m). \quad (32)$$

Fig. 8 shows the results for MgB_2 . Note that hybridization of π and σ electrons gives a common T_c .

The interplay of magnetism and superconductivity suggested already by the occurrence of superconductivity in the periodic table is, for several reasons, of utmost interest. This has, for example, been studied for (film) structures $N_1 | N_2 | N_3$. Results are given in Fig. 9.

Organic superconductors display, in particular, interesting dimensional structural effects and those due to charge-wave and magnetic instabilities. Also, astonishingly, superconductivity may be induced by strong magnetic fields. In Fig. 10, the interesting phase diagram of $\kappa\text{-(BEDT-TTF)}_2\text{-Cu[N(CN)}_2\text{]Br}$, a typical composition of a charge-transfer salt, is shown. Such molecules are stacked into layers. Planes of $\text{Cu[N(CN)}_2\text{]Br}$ anions separate these layers. Within these layers, the molecules form dimers and

electrons or holes can then hop easily from one molecule to the next one, but not perpendicular to the layers. The salts consist of conducting layers separated by a nonconducting environment (anions). Clearly, bond-length changes, also due to pressure, will sensitively change the electrical properties. Also, a magnetic field perpendicular to the layers (along the c -axis) affects the system due to the formation of Landau levels, which will pass the Fermi energy as the external magnetic field varies (cf. de Haas–van Alphen oscillations). In stronger magnetic fields quantum mechanical interband tunneling also occurs. Note that superconductivity occurs at relatively low temperatures, usually upon applying pressure. Experiments indicate unconventional Cooper pairing ($2\Delta_0 \sim 7k_B T_c$, non- s -symmetry of Δ_k). Whether phonons are involved in Cooper pairing must be clarified by further analysis.

In an external magnetic field, interesting behavior, such as Landau-level formation and spin-split bands, may result due to the layered structure. Possibly, Cooper pairs $((k\uparrow, -k+q\downarrow))$ may form. A Larkin–Ovchinnikov (LO) state with $\Delta_k \sim \cos(\mathbf{k} \cdot \mathbf{r})$ may occur. In general, the response to an external magnetic field is highly anisotropic. Furthermore, it is interesting that superconductivity may

be induced in λ -(BETS)₂FeCl₄ by a magnetic field h , which destroys long-range magnetic order of the Fe³⁺. Field-induced superconductivity may also occur in α -(BEDT-TTF)₂KHg(SCN)₄ by affecting the charge density wave (CDW) with the external magnetic field h . Further experiments are needed; however, rich behavior may be expected in general since CDW and SDW excitations, Landau levels, and 2D properties are present.

Superconductivity in small particles (radius R) due to electronic level discretization ($\delta_2 \approx \varepsilon_F/n \approx (\hbar v_F/R)$ ($k_F R$)⁻², $\xi \sim (R\delta/kT_c)(Rk_F)^2$), and charge fluctuations, $Q = en \Leftrightarrow Q \pm e$, as a result of single electron and Cooper pair hopping, exhibit interesting behavior.

The charging of small particles is controlled by electrostatic energy. The change of the charge $Q = en \rightarrow Q \pm e$ causes an energy change $e^2/2C$, where C is the capacitance of the small particle, leading to a Coulomb blockade (in tunneling, for example). At temperatures $T \simeq 0$, due to the electrostatic energy, it is ($\Delta Q = e\Delta n$)

$$E_n = \frac{Q^2}{2C} - \frac{Q}{C}C'V, \quad (33)$$

(C and C' are capacitances of a system including voltage contact and V is the external potential), and the blockade is periodically lifted as a function of n and V ($E_{n+1} = E_n$). In the superconducting state, one has for $T \simeq 0$ that $\Delta > e^2/2C$. The situation is illustrated in Fig. 11. From $E_{n+1} + \Delta = E_n$ and $E_{n+2} = E_n$, n even and large sea of Cooper pairs, a period doubling results, with respect to the normal state. Note that the equation $E_{n+2} = E_n$ might not hold for smaller density of Cooper pairs. In view of the strong quantum-mechanical behavior of small particles, structures consisting of a larger number of small particles seem very interesting (mesoscopic systems).

Fig. 11 Charging-up behavior of a small superconductor with capacitance C and charge $Q = en$, n even, in a potential V ($\Delta > e^2/2C$). This behavior follows from $E_n = E_{n+2}$ and reflects Cooper pair formation. One also has $E_n = E_{n+1} + \Delta$, where E_{n+1} refers to a state with one unpaired electron. Then Q changes by e at $\Delta V \propto (2n+1)$. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

Fig. 12 Transitions in an ensemble of superconducting quantum dots controlled by the Josephson-energy E_J and the Coulomb-energy $E_c = e^2/2C$. T_c refers to the global superconducting transition temperature of the ensemble. Phase O refers to a globally ordered superconducting state of the ensemble and phase d to superconducting grains with no global Cooper pair phase coherence, z is the coordination number. From Bennemann KH (2005) Superconductivity: BCS theory. In: Encyclopedia of Condensed Matter Physics, 1st edn., pp. 72–81. Amsterdam: Elsevier.

An ensemble of grains for illustration may exhibit transitions to superconductivity at T_{c1} , where the single grains get superconducting, and at T_{c2} , where the whole ensemble becomes superconducting ($T_{c2} \leq T_{c1}$) globally and phase coherently; see Fig. 12. Generally, an ensemble of grains may resemble an alloy-like array of S/S and S/N junctions (S = superconducting, N = normal state grains). The behavior of an ensemble of grains depends, of course, on the coupling and electron hopping between the grains. Also the structural order of the grains plays a role. A regular lattice-like arrangement of the grains (one-dimensional or two-dimensional topology) is of particular interest. For small distances between the cluster particles, electron tunneling and inelastic Cooper pair tunneling (Josephson coupling) occur. Hence, charge fluctuations are present in such granular superconductors. The resultant interesting Josephson effect can be described by

$$H = H_T - \sum_{ij} E_g(i, j) \cos \Phi_{ij} + \frac{2e^2}{C} \sum_{ij} (N_i - N_j)^2 + \dots \quad (34)$$

The first term refers to normal electron hopping between the grains, the second term to Cooper pairs tunneling between neighboring superconducting grains (Josephson effect), and the last term is the electrostatic energy due to different charges of neighboring grains i, j . For simplicity, the same capacitances C and E_J (Josephson energy) are used. The phase difference $\Phi_{ij} = \Phi_i - \Phi_j$ refers to the phases Φ_i of the superconducting order parameter $\Delta_i = |\Delta_i|e^{i\Phi_i}$ of grain i . It is important to note that $[\Phi, N] = i$, where N is the Cooper-pair number operator.

Conclusion

In conclusion, BCS superconductivity has been overviewed. While the basis of the BCS theory is well developed, details of the physics may have interesting consequences that have not been understood yet. New important discoveries can be expected. The relationship of phase-coherent and, in particular, phase-incoherent Cooper pairing with the Bose–Einstein condensation (BEC) is of fundamental interest. One expects, in particular, for more local pairing, perfect Boson behavior of the two paired electrons and thus an intimate relationship between Cooper pairing and BEC. Meissner-type superconductivity and BEC should result only for phase-coherent Cooper pairing.

The size of the Cooper pairs is of the order of the coherence length. For small superconductivity density, one may reach a state (also possibly achieved geometrically, e.g., in narrow pipes, granular superconductors, etc.) where the singlet Cooper pairs do not overlap and behave like Bosons and a BEC transition is expected (Bennemann and Ketterson, 2014). Near the crossover transition, anomalous behavior may occur, for example, in cuprate underdoped superconductors due to phase fluctuations. Applying the Heisenberg uncertainty relation, one gets that the product of phase and occupation is $\sim \hbar$ (Bennemann and Ketterson, 2014).

While for the cuprates the glue for Cooper pairing Phonons or Spin fluctuations is still debated, it seems that the essential structure of BCS theory is valid (namely Cooper pairs, Josephson current, order parameter equation with g positive or negative) (Bennemann, 2005).

Various properties of conventional and unconventional superconductors have been discussed. The general calculation of the superconducting transition temperature remains a problem. Also a discussion of other Cooper pairing mechanisms (spin fluctuation besides phonon-induced superconductivity) as well as triplet pairing like in He-3 is an open issue.

Abstract

Low temperature properties of superconducting nanowires are determined by quantum fluctuations. Both Gaussian fluctuations of the superconducting phase—associated with plasma modes propagating along the wire—and non-Gaussian fluctuations of the order parameter—quantum phase slips—are equally important being responsible, e.g., for a “superconductor-insulator” quantum phase transition governed by the wire diameter. Thicker (“superconducting”) nanowires demonstrate non-vanishing resistance and shot noise of the voltage caused by quantum phase slips. Thinner (“insulating”) nanowires become truly insulating only at scales exceeding a non-perturbative localization length for Cooper pairs, whereas at shorter length scales they still exhibit superconducting properties.

Key points

- Microscopic theory of superconducting fluctuations, proliferation of quantum phase slips in superconducting nanowires, description of quantum properties of “superconducting” and “insulating” phases.

Introduction

A vast majority of properties of bulk conventional superconductors is perfectly described by the standard Bardeen-Cooper-Schrieffer (BCS) theory operating with complex order parameter $\Delta = |\Delta| \exp(i\varphi)$ within the mean field approach (Tinkham, 1996). Superconducting fluctuations play little role here and, hence, macroscopic phase coherence usually remains well preserved over the whole sample.

Unlike in bulk superconductors, fluctuations become far more important in lower dimension where—according to the well known Mermin-Wagner-Hohenberg theorem—fluctuations of the superconducting phase φ should destroy the long-range order, i.e., long-range phase coherence. Fortunately, this formal observation does not yet imply that low dimensional systems cannot exhibit superconducting properties. This is because any generic superconducting system has a finite size in which case phase coherence can survive at least to a certain extent. For instance, two-dimensional (2D) superconducting films are known to undergo Berezinskii-Kosterlitz-Thouless (BKT) topological phase transition. As a result, the decay of superconducting correlations in such films changes from exponential at higher temperatures T to power law at lower ones, implying that at low enough T long range phase coherence remains essentially preserved in samples of a finite size. Hence, generic 2D metallic films can and do turn superconducting.

Does superconductivity also survive in quasi-one-dimensional (1D) wires or do phase fluctuations disrupt supercurrent in such systems? The answer to this question is of both fundamental interest and practical importance due to rapidly progressing miniaturization of superconducting circuits employed in a broad range of applications, such as, e.g., quantum nanoelectronics, quantum information and metrology. As we will see below, superconducting fluctuations play a crucial role in 1D wires and essentially determine both their transport and ground state properties. The behavior of superconducting nanowires turns out to be rich, complex and highly interesting.

Fig. 1 Schematics of small fluctuations of the order parameter (upper panel) and the phase slip process (lower panel) in superconducting nanowires. During the latter process the absolute value of the order parameter Δ gets locally and temporarily suppressed due to thermal and/or quantum fluctuations while its phase φ suffers a jump by 2π . Adapted from Semenov AG and Zaikin AD (2022) Superconducting quantum fluctuations in one dimension. *Physics-Uspokhi* 65: 945–983.

Superconducting fluctuations

Thermal and quantum fluctuations may cause deviations of both the modulus and the phase of the superconducting order parameter $\Delta(x)$ (with x being the coordinate along the wire) from their mean field values. One can distinguish (i) small (Gaussian) fluctuations of the order parameter and (ii) non-Gaussian fluctuations, i.e., the so-called *phase slips* (Arutyunov et al., 2008; Bezryadin, 2013; Zaikin, 2010; Zaikin and Golubev, 2019). These two kinds of fluctuations are schematically illustrated in Fig. 1.

The strength of fluctuation effects in superconducting nanowires is essentially controlled by two different parameters, dimensionless conductance g_ξ and dimensionless admittance g_Z . These parameters are defined as

$$g_\xi = R_q/R_\xi, \quad g_Z = R_q/Z_w, \quad (1)$$

where $R_q = 2\pi/e^2 \simeq 25.8 \text{ K}\Omega$ is the quantum resistance unit, R_ξ is the normal state resistance of the wire segment of length equal to the superconducting coherence length ξ , $Z_w = \sqrt{\mathcal{L}/\mathcal{C}}$ is the wire impedance, $\mathcal{L} = 1/(\pi\sigma_N\Delta_0 s)$ and $\mathcal{C}$ are respectively the kinetic wire inductance (times length) and the geometric wire capacitance (per length), σ_N is the normal state Drude conductance of the wire and s is the wire cross section. Both parameters (1) scale with the wire cross section as $g_\xi \propto s$ and $g_Z \propto \sqrt{s}$. Note that here and below for simplicity and compactness we set the Planck constant $\hbar$, the Boltzmann constant k_B and the speed of light c equal to unity. If necessary, these parameters can easily be restored at any stage of our analysis.

In generic metallic nanowires the dimensionless conductance g_ξ typically strongly exceeds unity. In this case one can demonstrate that small (Gaussian) fluctuations of both the absolute value and the phase of the order parameter yield only a small ($\propto 1/g_\xi$) fluctuation correction to the BCS (mean field) value of this parameter Δ_0 . In particular, at $T \rightarrow 0$ one has (Zaikin, 2010; Zaikin and Golubev, 2019)

$$\Delta = \Delta_0 - \delta\Delta_0, \quad \frac{\delta\Delta_0}{\Delta_0} \sim \frac{1}{g_\xi} \sim Gi_{1D}^{3/2}. \quad (2)$$

Here Gi_{1D} is the so-called Ginzburg number (Larkin and Varlamov, 2005) which controls the fluctuation region in the immediate vicinity of the BCS critical temperature T_C . Eq. (2) demonstrates that at low T the order parameter suppression due to Gaussian fluctuations may become significant only in extremely thin nanowires with $Gi_{1D} \sim 1$ and $g_\xi \sim 1$.

It turns out that in the limit $g_\xi \gg 1$ Gaussian phase fluctuations in superconducting wires are practically decoupled from those of $|\Delta|$. Such phase fluctuations are controlled by the parameter g_Z (1) and are intimately related to sound-like plasma modes (the so-called Mooij-Schön modes) propagating along superconducting wires with the velocity $v = 1/\sqrt{\mathcal{L}\mathcal{C}}$. As we will see below, the presence of such plasma modes is crucially important and to a large extent determines the physics of superconducting nanowires at low temperatures.

Turning to non-Gaussian fluctuations of the order parameter illustrated in lower panel of Fig. 1, we observe that the phase slip process corresponds to temporal suppression of $|\Delta(x)|$ down to zero in some point $x = x_0$ inside the wire. As soon as the modulus of the order parameter $|\Delta(x_0)|$ vanishes, the phase $\varphi(x_0)$ becomes unrestricted and can jump by 2π . After that $|\Delta(x_0)|$ gets restored, the phase becomes single valued again and the system returns to its initial state accumulating the net phase shift 2π .

According to the Josephson relation each such phase jump—depending on its sign—implies positive or negative voltage pulse $\delta V = \dot{\varphi}/2e$. In the absence of any bias current the average number of “positive” voltage pulses is exactly equal to that of the “negative” ones. Hence, the net voltage drop across the wire remains zero. Applying the current $I \propto |\Delta|^2 \nabla \varphi$ one creates nonzero phase gradient along the wire, thereby breaking the symmetry between “positive” and “negative” phase slips and making the former to prevail over the latter (or vice versa). As a result, the net voltage drop V across the wire now differs from zero. Hence, phase slips should cause non-zero resistance $R = V/I$ of 1D superconducting wires at temperatures below T_C .

At T just slightly below T_C phase slips occur predominantly due to thermal fluctuations of the order parameter. Creation rate of such thermally activated phase slips (TAPS) and, hence, the wire resistance R below T_C are determined by the activation exponent, i.e.,

$$R(T) \propto \exp(-\delta F/T), \quad \delta F \sim \frac{N_0 \Delta_0^2(T)}{2} s \xi(T), \quad (3)$$

where the free energy difference δF plays the role of an effective potential barrier for TAPS determined by the superconducting condensation energy $N_0 \Delta_0^2/2$ (N_0 being the normal electron density of states) within the volume $\sim s \xi(T)$ of the wire segment where superconductivity is destroyed by thermal fluctuations. At temperatures close to T_C Eq. (3) yields appreciable resistivity which was indeed detected in experiments performed on small superconducting whiskers with typical diameters $\sim 0.5 \mu\text{m}$. However, as the temperature is lowered considerably below T_C the TAPS rate decreases exponentially and no measurable wire resistance is predicted by Eq. (3) in the limit of low T .

In this limit quantum fluctuations of the order parameter should take over. As we already indicated, significant non-Gaussian quantum fluctuations in such wires are quantum phase slips (QPS). Each QPS event involves suppression of the order parameter in the phase slip core and a winding of its phase around this core. This configuration describes quantum tunneling of the order parameter field $\Delta(x)$ through an effective potential barrier $\sim \delta F$. The probability of such tunneling process turns out to be negligible for thicker wires. However, recent progress in nanolithographic technique allowed to fabricate samples with much smaller diameters down to—and even below—10 nm. In this case the potential barrier $\delta F \propto s$ becomes much lower and the QPS tunneling rate increases dramatically enabling quantum phase slips to dominate low temperature behavior of superconducting nanowires.

Quantum phase slips

While the TAPS rate at T close to T_C can be estimated employing just a simple Ginzburg-Landau-type of approach, theoretical analysis of QPS effects requires a much more complicated theory describing full quantum dynamics of the superconducting order parameter field at any temperature down to $T = 0$. This theory is constructed in the spirit of the celebrated Feynman-Vernon-Caldeira-Leggett influence functional technique (Zaikin, 2010; Zaikin and Golubev, 2019).

The starting point is the microscopic Hamiltonian $\hat{H}$ for electrons in a superconductor that includes a short range attractive BCS and a long range repulsive Coulomb interactions as well as electromagnetic fields. With the aid of the Hubbard-Stratonovich transformations one decouples these interaction terms and introduces the fluctuating order parameter field Δ and the fluctuating scalar potential V . Integrating out all electronic degrees of freedom, one arrives at the grand partition function $\mathcal{Z}$ expressed in terms of the path integral

$$\mathcal{Z} = \text{Tr} \exp(-\hat{H}/T) = \int \mathcal{D}^2 \Delta \mathcal{D} V \mathcal{D} \mathbf{A} e^{-S_{\text{eff}}}. \quad (4)$$

The gauge invariant effective action reads

$$S_{\text{eff}} = -\text{Tr} \ln \mathcal{G}^{-1} + S_0[V, \mathbf{A}, \Delta]. \quad (5)$$

Here $\mathbf{A}$ is the electromagnetic vector potential and

$$\mathcal{G}^{-1} = \begin{pmatrix} \partial_\tau + \xi(\nabla) - ie\Phi + \frac{m\mathbf{v}_s^2}{2} - \frac{i}{2}\{\nabla, \mathbf{v}_s\} & |\Delta| \\ |\Delta| & \partial_\tau - \xi(\nabla) + ie\Phi - \frac{m\mathbf{v}_s^2}{2} - \frac{i}{2}\{\nabla, \mathbf{v}_s\} \end{pmatrix},$$

where $\xi(\nabla) \equiv -\nabla^2/2m - \mu + U(x)$ describes a single conduction band with quadratic dispersion and also includes an arbitrary impurity potential $U(x)$ and the curly brackets denote the anticommutator. We also introduce the gauge invariant linear combinations

$$\Phi = V - \frac{\dot{\varphi}}{2e}, \quad \mathbf{v}_s = \frac{1}{2m} \left(\nabla \varphi - \frac{2e}{c} \mathbf{A} \right), \quad (6)$$

which define the so-called chemical potential of Cooper pairs Φ and the superconducting velocity $\mathbf{v}_s$.

Quantum phase slip configuration represents a nontrivial saddle point of the action (5). It is a formidable task to explicitly find this saddle point for the full nonlinear effective action S_{eff} . Obviously, this task can hardly be accomplished in practice. On the other

hand, the problem becomes simpler provided one is interested in estimating the QPS effective action S_{qps} up to a numerical prefactor of order one. For that purpose we can resort to several approximations.

Specifically, we perform a perturbative expansion of the action up to the second order in Φ , $\mathbf{v}_s$ and the fluctuating part of the order parameter $\delta\Delta(x, \tau) = |\Delta(x, \tau)| - \Delta_0$ around its equilibrium value Δ_0 . In addition, we average over the random potential of impurities. After this step the effective action becomes translationally invariant both in space and in time. Integrating out V and $\mathbf{A}$ -fields we identically rewrite our partition function and the effective action only in terms of the fluctuating variables $\delta\Delta$ and φ . Then performing the Fourier transformation with respect to both x and τ , expanding the action in powers of ω and q^2 up to terms $\sim \omega^2 q^2$ and rewriting the action again in the space-time domain, we obtain

$$S_{\text{eff}} \simeq \int dx d\tau \left\{ \frac{C}{8e^2} \left(\frac{\partial \varphi}{\partial \tau} \right)^2 + \frac{1}{8e^2 \mathcal{L}} \left(\frac{\partial \varphi}{\partial x} \right)^2 + \frac{\pi \sigma_N s}{64e^2 \Delta_0} \left(\frac{\partial^2 \varphi}{\partial x \partial \tau} \right)^2 + s N_0 \delta\Delta^2 + \frac{s N_0}{12 \Delta_0^2} \left(\frac{\partial \delta\Delta}{\partial \tau} \right)^2 + \frac{\pi s N_0 D}{8 \Delta_0} \left(\frac{\partial \delta\Delta}{\partial x} \right)^2 \right\}, \quad (7)$$

where D is the normal state diffusion constant. The first two terms under the integrals of Eq. (7) describe phase fluctuations corresponding to Mooij-Schön plasma modes, the third term $\sim \sigma_N (\nabla \varphi)^2$ has to do with “gapped” dissipation inside the wire and is reminiscent of that describing capacitance renormalization due to retardation effects in Josephson junctions, while the last three terms account for the loss of the condensation energy due to fluctuations of $|\Delta|$.

It is convenient to separate the action for a single QPS S_{qps} into a core part S_{core} and that originating from outside the core S_{out} , which depends on the hydrodynamics of the electromagnetic fields, i.e.,

$$S_{\text{qps}} = S_{\text{core}} + S_{\text{out}}. \quad (8)$$

Let us denote the QPS core size as x_0 and the (imaginary) time duration of the QPS event as τ_0 . At this stage both these parameters are not yet known and remain to be determined from our subsequent analysis.

We first evaluate the hydrodynamic part S_{out} . Outside the QPS core only the phase variable φ fluctuates both in space and in time while $|\Delta| = \Delta_0$ does not. Then the saddle point solution $\tilde{\varphi}(x, \tau)$ corresponding to a single QPS event should satisfy the identity

$$\partial_x \partial_\tau \tilde{\varphi} - \partial_\tau \partial_x \tilde{\varphi} = 2\pi \delta(\tau, x) \quad (9)$$

implying that after a wind around the QPS center (assumed to be located at $\tau = 0$ and $x = 0$) the phase should change by 2π . We observe that QPS is just equivalent to a vortex in space-time with the phase distribution $\varphi(x, \tau)$ described by the saddle point solution

$$\tilde{\varphi}(x, \tau) = -\arctan(x/v\tau). \quad (10)$$

Substituting the solution (10) into the action (7), we obtain

$$S_{\text{out}} = \lambda \ln[\min(L, v/T)/\max(x_0, v\tau_0)], \quad (11)$$

where the parameter $\lambda = g_Z/8$ sets the scale for the hydrodynamic part of the QPS action, L is the wire length.

Let us now turn to the core term S_{core} . As we are anyway aiming at evaluating this term up to a numerical prefactor of order one, without loss of generality we may approximate the order parameter field inside the QPS core by two simple functions

$$\delta\Delta(x, \tau) = \Delta_0 \exp(-x^2/2x_0^2 - \tau^2/2\tau_0^2), \quad (12)$$

$$\varphi(x, \tau) = -(\pi/2) \tanh(x\tau_0/x_0\tau). \quad (13)$$

These functions obey all necessary requirements, the most important of which are: (i) the magnitude of the order parameter $\Delta(x, \tau)$ vanishes at $x = 0$ and $\tau = 0$ and coincides with the mean field value Δ_0 outside the QPS core at $|x| \gtrsim x_0/2$, $|\tau| \gtrsim \tau_0/2$ and (ii) the phase $\varphi(x, \tau)$ flips at $x = 0$ and $\tau = 0$ in a way to provide the change of the net phase difference across the wire by 2π . Note that the choice of the trial functions (12), (13) is by no means restrictive for our purposes, almost any other sufficiently smooth function obeying the above requirements can be used to estimate S_{core} within the required accuracy.

Substituting the functions (12), (13) into the action (7), setting $\sigma_N = 2e^2 N_0 D$ and minimizing the resulting expression for S_{core} with respect to x_0 and τ_0 , we arrive at the final results both for the core parameters

$$x_0 \sim \xi = \sqrt{D/\Delta_0}, \quad \tau_0 \sim 1/\Delta_0 \quad (14)$$

and for the core action

$$S_{\text{core}} = a g_\xi \sim N_0 s \sqrt{D \Delta_0}. \quad (15)$$

Note that during this minimization procedure we neglected the contribution S_{out} (11) to the total QPS action S_{qps} (8). This is appropriate because the two contributions to the QPS action depend differently on the wire thickness, i.e., $S_{\text{core}} \propto \mathcal{N}$ and $S_{\text{out}} \propto \sqrt{\mathcal{N}}$, where $\mathcal{N} = p_F^2/4\pi$ defines the total number of conducting channels in the wire and p_F is the Fermi momentum. Hence, for generic metallic wires with $\mathcal{N} \gg 1$ one usually has $S_{\text{core}} \gg S_{\text{out}}$. In addition, one can verify that the results (14) and (15)

hold for not too long wires with lengths $L \lesssim \xi N$. The latter condition is satisfied in a vast majority of experiments with superconducting nanowires.

We also point out that minimization of the “condensation energy” contribution $\sim \delta \Delta^2$ (the last three terms in Eq. (7)) alone already yields the correct estimate for $S_{\text{core}} \sim N_0 s \sqrt{D \Delta_0}$. This observation, however, by no means implies that phase fluctuations terms in Eq. (7) can be neglected. Just on the contrary, phase fluctuations yield exactly the same order-of-magnitude estimate for S_{core} provided one keeps “gapped” dissipation term $\sim \sigma_N (\nabla \dot{\varphi})^2$ with the Drude expression $\sigma_N = 2e^2 N_0 D$. At the same time, e.g., ignoring this term by formally setting $\sigma_N \rightarrow 0$ in Eq. (7) during our minimization procedure would immediately yield meaningless results for x_0 and τ_0 as well as the QPS action parametrically different from that in Eq. (15).

The result (15) allows to recover the QPS tunneling amplitude γ_{qps} within the exponential accuracy. Evaluating the contribution of fluctuations around the QPS saddle point one gets (Zaikin and Golubev, 2019)

$$\gamma_{\text{qps}} \sim (g_\xi \Delta_0 / \xi) \exp(-a g_\xi), \quad (16)$$

where g_ξ is supposed to be much larger than one and the prefactor $a \sim 1$ can be regarded as a fit parameter, which can be extracted, e.g., from the available experimental data. The QPS amplitude (16) will play a prominent role in our subsequent analysis.

Quantum phase transition

Although the hydrodynamic part of the action (11) and the parameter λ do not enter directly into the expression for the QPS amplitude γ_{qps} (16), they also play an important role, as they determine interactions between different quantum phase slips mediated by plasmon modes propagating along the wire.

Consider the configuration of n phase slips essentially equivalent to n vortices in space-time with the corresponding core coordinates (x_i, τ_i) . Provided the phase slip cores do not overlap with each other the core contributions are independent and simply add up. In order to evaluate the hydrodynamic part we substitute the superposition of the saddle point solutions for n quantum phase slips $\varphi = \sum_i^n \tilde{\varphi}_i(x - x_i, \tau - \tau_i)$ into the action. Then we get $S_{\text{QPS}}^{(n)} = n S_{\text{core}} + S_{\text{int}}^{(n)}$, where

$$S_{\text{int}}^{(n)} = -\lambda \sum_{i \neq j} v_i v_j \ln \left(\frac{\rho_{ij}}{x_0} \right) + \frac{\Phi_0}{c} I \sum_i v_i \tau_i. \quad (17)$$

Here $\rho_{ij} = (v^2(\tau_i - \tau_j)^2 + (x_i - x_j)^2)^{1/2}$ defines the distance between the i -th and j -th QPS in the (x, τ) plane and $v_i = \pm 1$ are QPS topological charges which fix the sign of the phase change after a wind around the QPS center. In Eq. (17) for simplicity we assumed $x_0 \sim v\tau_0$ and included an additional term which keeps track of the total current I possibly flowing across the wire. We observe that different quantum phase slips interact logarithmically in space-time attracting (repelling) each other in the case of opposite (equal) topological charges.

The grand partition function of the wire $\mathcal{Z}$ is represented as a sum over all possible QPS configurations:

$$\begin{aligned} \mathcal{Z} = & \sum_{n=0}^{\infty} \frac{1}{2n!} \left(\frac{\gamma}{2} \right)^{2n} \int_{x_0}^L \frac{dx_1}{x_0} \dots \int_{x_0}^L \frac{dx_{2n}}{x_0} \\ & \times \int_{\tau_0}^{1/T} \frac{d\tau_1}{\tau_0} \dots \int_{\tau_0}^{1/T} \frac{d\tau_{2n}}{\tau_0} \sum_{v_i=\pm 1} e^{-S_{\text{int}}^{(2n)}}, \end{aligned} \quad (18)$$

where $\gamma = x_0 \tau_0 \gamma_{\text{qps}}$ is an effective QPS fugacity. The sum in Eq. (18) runs over neutral QPS configurations with $\sum_i^{2n} v_i = 0$, which is a direct consequence of the boundary condition $\varphi(x, \tau) = \varphi(x, \tau + 1/T)$ in the corresponding path integral for $\mathcal{Z}$.

In the limit $I \rightarrow 0$ Eqs. (17) and (18) define the standard model for a 2D gas of logarithmically interacting charges v_i . Making use of the standard BKT renormalization group (RG) analysis of logarithmically interacting 2D Coulomb gas we arrive at the scaling equations for the interaction parameter λ and the charge fugacity γ :

$$\partial_\Lambda \lambda = -4\pi^2 \lambda^2 \gamma^2, \quad \partial_\Lambda \gamma = (2 - \lambda) \gamma. \quad (19)$$

Here $\Lambda = \ln(\rho/x_0)$ is the scaling parameter.

Following the standard line of reasoning we immediately conclude that a quantum phase transition (QPT) for phase slips occurs in a long superconducting wire at $T \rightarrow 0$ and

$$\lambda = 2 + 4\pi\gamma \simeq 2. \quad (20)$$

This is nothing but BKT-like phase transition for topological charges v_i in space-time (Zaikin and Golubev, 2019). The difference from the standard BKT transition in 2D superconducting films is that in our case the transition is driven by the interaction parameter $\lambda = g_Z/8\alpha\sqrt{s}$ and not by temperature.

For thicker wires with $\lambda > 2$ (corresponding to the “ordered” phase) QPS with opposite topological charges are bound in pairs (dipols) thereby limiting the effect of quantum fluctuations, whereas in thinner ones with $\lambda < 2$ (“disordered” phase) the density of free (unbound) QPS always remains nonzero implying that long range phase coherence gets destroyed in this case. Below we will demonstrate that this QPT can be interpreted as a superconductor-insulator phase transition with rather non-trivial features of both “superconducting” and “insulating” phases.

Phase-charge duality

Before we turn to this issue let us establish an important property of superconducting nanowires which is the so-called phase-charge duality.

To begin with, we note that duality between the phase and the charge variables is a well known property of Josephson junctions. In particular, under a certain duality transformation the effective actions for Josephson tunnel junctions in the phase and in the charge representations are exactly transformed onto each other (Schön and Zaikin, 1990). Furthermore, in the absence of an external circuit the Josephson junction can be described in terms of an effective Hamiltonian for a “quantum particle” in the periodic potential in the (quasi)-charge space. Within this picture, the charge Q and the flux Φ are canonically conjugate variables fully analogous to the momentum and coordinate variables in quantum mechanics.

Similar duality ideas can be worked out and applied to superconducting nanowires (Semenov and Zaikin, 2022). To this end, let us for simplicity assume that our superconducting wire is isolated from any external circuit and ignore for a moment all kinds of fluctuations of the absolute value of the order parameter including, of course, quantum phase slips. In this case only phase fluctuations remain and the wire effective action with a high accuracy can be described by the terms in the first line of Eq. (7). Then the effective Hamiltonian of the wire reduces to that of a transmission line

$$\hat{H}_{\text{TL}} = \int_0^L dx \left[\frac{\hat{Q}^2(x)}{2C} + \frac{1}{2L} \left(\frac{\partial_x \hat{\varphi}(x)}{2e} \right)^2 \right], \quad (21)$$

where $\hat{Q}(x)$ and $\hat{\varphi}(x)$ are canonically conjugate local charge and phase operators obeying the commutation relations

$$[\hat{Q}(x), \hat{\varphi}(x')] = -2ie\delta(x-x'). \quad (22)$$

These operators can also be expressed as

$$\hat{Q}(x) = \frac{1}{\Phi_0} \partial_x \hat{\chi}(x), \quad \partial_x \hat{\varphi}(x) = 2e\hat{\Phi}(x), \quad (23)$$

where $\hat{\chi}(x)$ and $\hat{\Phi}(x)$ represent some new (dual) operators. Combining Eqs. (21) and (23), we obtain

$$\hat{H}_{\text{TL}} = \int_0^L dx \left[\frac{\hat{\Phi}^2(x)}{2L} + \frac{1}{2C} \left(\frac{\partial_x \hat{\chi}(x)}{\Phi_0} \right)^2 \right]. \quad (24)$$

The physical meaning of both dual operators is transparent from Eqs. (23) and (24), i.e., $\hat{\Phi}(x)$ is the local flux operator, while $\hat{\chi}(x)$ is proportional to the operator for electric charge passed through the point x .

Let us now include quantum phase slips into our consideration. With the aid of a rigorous calculation one can demonstrate that the total effective wire Hamiltonian in the presence of QPS takes the form

$$\hat{H}_{\text{wire}} = \hat{H}_{\text{TL}} - \gamma_{\text{qps}} \int_0^L dx \cos(\hat{\chi}(x)), \quad (25)$$

where $\hat{H}_{\text{TL}}$ is defined in Eq. (24). Evaluating the partition function $\mathcal{Z} = \text{Tr} \exp(-\hat{H}_{\text{wire}}/T)$ with the Hamiltonian (25) and expanding in powers of γ_{qps} one immediately recovers Eq. (18).

Let us now take a look at Fig. 2 displaying two complementary superconducting devices. One of them is an arbitrarily long superconducting nanowire surrounded by the vacuum or an insulator (upper part of the figure). In the device depicted in the lower part of the figure the superconductor is interchanged with the vacuum/insulator, thus forming a spatially extended Josephson junction between two superconductors. A superconducting nanowire in Fig. 2 is described by the Hamiltonian (25), whereas the Hamiltonian corresponding to a Josephson junction (of length L) in Fig. 2 has the well known form

$$\hat{H}_{\text{JJ}} = \int_0^L dx \left[\frac{\hat{Q}^2(x)}{2C_J} + \frac{1}{2L_J} \left(\frac{\partial_x \hat{\phi}(x)}{2e} \right)^2 \right] - \frac{j_C}{2e} \int_0^L dx \cos \hat{\phi}(x), \quad (26)$$

where $\hat{Q}(x)$ and $\hat{\phi}(x)$ are the local charge and phase difference operators, C_J and L_J represent respectively the Josephson junction capacitance and inductance per unit junction length and, finally, j_C is the Josephson critical current density. Under the transformation of the operators

$$\hat{\Phi}(x) \leftrightarrow \hat{Q}(x), \quad \hat{\chi}(x) \leftrightarrow \hat{\phi}(x) \quad (27)$$

the Hamiltonians $\hat{H}_{\text{wire}}$ and $\hat{H}_{\text{JJ}}$ are *exactly dual* to each other provided we interchange

$$\Phi_0 \leftrightarrow 2e, \quad \gamma_{\text{QPS}} \leftrightarrow \frac{j_C}{2e}, \quad L \leftrightarrow C_J, \quad C \leftrightarrow L_J. \quad (28)$$

The above duality transformations—on one hand—interchange magnetic and charging energies in these two Hamiltonians and—on the other hand—establish the correspondence between the last term in Eq. (25) describing the effect of QPS and the Josephson coupling energy in the second line in Eq. (26) that accounts for Cooper pair tunneling across the junction.

Fig. 2 Dual tunneling processes for a quantum fluxon (that tunnels through a superconducting nanowire) and for a Cooper pair (which tunnels across a Josephson junction). Fig. 3 The system under consideration. Adapted from Semenov AG and Zaikin AD (2022) Superconducting quantum fluctuations in one dimension. *Physics-Uspekhi* 65: 945–983.

Hence, tunneling of a Cooper pair with charge $2e$ between two superconductors is a dual process to a QPS event that can also be viewed as tunneling of a flux quantum Φ_0 across a superconducting wire. Indeed, the last term in the Hamiltonian (25) contains a linear combination of creation ($e^{i\hat{\varphi}}$) and annihilation ($e^{-i\hat{\varphi}}$) operators for the flux quantum Φ_0 . Each QPS event corresponds to the net phase jump by 2π associated with voltage pulse $\delta V = \dot{\varphi}/2e$ and magnetic flux $\int |\delta V(t)| dt = \Phi_0$ passing through the wire in the direction normal to its axis, as it is illustrated in Fig. 2.

“Superconducting” regime: Dissipative transport and noise

Let us examine the properties of superconducting nanowires in the “ordered” phase $\lambda > 2$ where QPS are bound in pairs and, hence, phase fluctuations are largely suppressed. These properties turn out to differ drastically from those of bulk superconductors (Semenov and Zaikin, 2022; Zaikin and Golubev, 2019).

Let us consider the circuit depicted in Fig. 3. It consists of a superconducting nanowire, an external capacitance C switched in parallel to this wire and the voltage source V_x applied via resistor R_x . The voltage $V(t)$ at the left end of the wire $x = 0$ fluctuates and can be measured by a detector while its right end ($x = L$) is grounded.

An effective Hamiltonian for this system can be written in the form

$$\hat{H} = \hat{H}_{\text{wire}} - I\varphi/2e + \frac{1}{2C} \left(-i \frac{\partial}{\partial(\varphi/2e)} + Q \right)^2, \quad (29)$$

where the term $\hat{H}_{\text{wire}}$ is defined in Eqs. (24) and (25) and describes the superconducting wire, whereas the second and third terms in the right-hand side of Eq. (29) account respectively for the potential energy tilt produced by an external current $I = V_x/R_x$ and for the charging energy. The variable $\varphi(t) \equiv \varphi(0, t)$ represents the phase of the order parameter field $\Delta(x, t)$ at $x = 0$ and the charge Q equals to $Q(t) = \chi(0, t)/\Phi_0$. Here we also set $\varphi(L, t) \equiv 0$.

In order to proceed it is convenient to make use of the Keldysh path integral technique, thus defining our variables of interest on the forward (F) and backward (B) time branches of the Keldysh contour, i.e., we now have $\varphi_F, B(t)$ and $\chi_F, B(x, t)$. We also introduce

“classical” and “quantum” variables, respectively $\varphi_+(t) = (\varphi_F(t) + \varphi_B(t))/2$ and $\varphi_-(t) = \varphi_F(t) - \varphi_B(t)$ (and similarly for the χ -fields). Making use of the Josephson relation between the voltage and the phase one can formally express the expectation value for the (symmetrized with respect to time moments) product of n voltage operators in the form

$$\langle V(t_1)V(t_2)\dots V(t_n) \rangle = \frac{\langle \dot{\varphi}_+(t_1)\dot{\varphi}_+(t_2)\dots\dot{\varphi}_+(t_n)e^{iS_{\text{qps}}} \rangle_0}{(2e)^n}, \quad (30)$$

where

$$S_{\text{qps}} = -2\gamma_{\text{qps}} \int dt \int_0^L dx \sin(\chi_+) \sin(\chi_-/2) \quad (31)$$

and

$$\langle \dots \rangle_0 = \int \mathcal{D}^2\varphi(t) \mathcal{D}^2\chi(x,t) (\dots) e^{iS_0[\varphi,\chi]} \quad (32)$$

implies averaging with the Keldysh effective action S_0 corresponding to the Hamiltonian $\hat{H}$ (29) with $\gamma_{\text{qps}} = 0$. The above formally exact expressions describe complete statistics of voltage fluctuations across superconducting nanowires.

Provided $\lambda > 2$ the expectation values (30) can be evaluated perturbatively in γ_{qps} . In the zero order in γ_{qps} all averages can be handled exactly. Expanding Eq. (30) up to the second order in γ_{qps} and performing all necessary averages we arrive at the results for voltage correlators of an arbitrary order.

In particular, for the expectation value of the voltage operator we obtain

$$\langle V \rangle = \frac{\Phi_0 L \gamma_{\text{qps}}^2}{4} \varsigma^2 \left(\frac{\Phi_0 I}{2} \right) \sinh \left(\frac{\Phi_0 I}{2T} \right), \quad (33)$$

where

$$\varsigma(\omega) = \tau_0^\lambda (2\pi T)^{\lambda-1} \frac{\Gamma(\frac{\lambda}{2} - \frac{i\omega}{2\pi T}) \Gamma(\frac{\lambda}{2} + \frac{i\omega}{2\pi T})}{\Gamma(\lambda)} \quad (34)$$

and $\Gamma(x)$ is the Euler Gamma-function. Evaluating the wire resistivity ρ from the above equations we get

$$\rho = \langle V \rangle / (IL) \propto \begin{cases} \gamma_{\text{qps}}^2 T^{2\lambda-3}, & T \gg \Phi_0 I, \\ \gamma_{\text{qps}}^2 I^{2\lambda-3}, & T \ll \Phi_0 I. \end{cases} \quad (35)$$

These results imply that due to QPS effects charge transport across our nanowires remains *dissipative* even in the “superconducting” phase $\lambda > 2$: The linear wire resistance tends to zero only at $T \rightarrow 0$, whereas its nonlinear resistance remains non-zero down to $T = 0$. This effect remains weak only for sufficiently thick nanowires with very large values of g_ξ (in which case γ_{qps} is vanishingly small) but becomes progressively more important for thinner nanowires. It is also worth pointing out that the key dissipation mechanism in this case is associated with Mooij-Schön plasma modes playing the role of an effective quantum bath for electrons inside the wire.

Quantum phase slips cause not only non-vanishing wire resistance but also voltage fluctuations. In order to quantify our description of such fluctuations we will analyze the voltage-voltage correlation function which can also be recovered from Eqs. (30)–(32) within the framework of the same perturbative in γ_{qps} approach. Let us define the noise power spectrum S_Ω which perturbative expression consists of three different contributions:

$$S_\Omega = \int dt e^{i\Omega t} \langle V(t)V(0) \rangle = S_\Omega^{(0)} + S_\Omega^r + S_\Omega^a. \quad (36)$$

The first of these contributions $S_\Omega^{(0)}$ has nothing to do with QPS and just defines equilibrium voltage noise for a transmission line. The other two terms are due to QPS effects. In the zero bias limit $I \rightarrow 0$ the term S_Ω^a vanishes, and the equilibrium noise spectrum $S_\Omega = S_\Omega^{(0)} + S_\Omega^r$ is determined from the fluctuation-dissipation theorem.

At non-zero bias values the QPS noise turns non-equilibrium. In the zero frequency limit $\Omega \rightarrow 0$ the terms $S_\Omega^{(0)}$ and S_Ω^r tend to zero, and the voltage noise $S_{\Omega \rightarrow 0} \equiv S_0$ is determined solely by S_Ω^a which yields

$$S_0 = \Phi_0 \coth \left(\frac{\Phi_0 I}{2T} \right) \langle V \rangle, \quad (37)$$

where $\langle V \rangle$ is specified in Eqs. (33) and (34). Hence, we obtain

$$S_0 \propto \begin{cases} T^{2\lambda-2}, & T \gg \Phi_0 I, \\ I^{2\lambda-2}, & T \ll \Phi_0 I. \end{cases} \quad (38)$$

At higher temperatures $T \gg \Phi_0 I$ Eq. (38) reduces to equilibrium voltage noise $S_0 = 2TR$ of a linear Ohmic resistor $R = \rho L$. In the opposite low temperature limit $T \ll \Phi_0 I$ it accounts for QPS-induced *shot noise* $S_0 = \Phi_0 \langle V \rangle$ obeying *Poisson statistics* with an effective “charge” equal to the flux quantum Φ_0 .

This result sheds light on the physical origin of shot noise in superconducting nanowires: It is produced by coherent tunneling of magnetic flux quanta Φ_0 across the wire. As we have already learned, such flux quanta can be viewed as charged quantum “particles” (fluxons) passing through (and being scattered at) an effective spatially extended “tunnel” barrier which role is played by a nanowire.

It is also interesting to analyze voltage noise produced by QPS at non-zero frequencies. In the limit of sufficiently high frequencies and/or long wires $v/L \ll \Omega \ll \Delta_0$ we obtain

$$S_{\Omega}^{(0)} = \frac{\lambda}{8\pi e^2} \frac{\Omega \coth\left(\frac{\Omega}{2T}\right)}{(\Omega/2E_C)^2 + (\lambda/\pi)^2}. \quad (39)$$

This contribution does not depend on the wire length L . At low T and $\Omega/\lambda \gtrsim E_C = e^2/2C$ we have $S_{\Omega}^{(0)} \propto 1/\Omega$, i.e., in this regime the wire may generate $1/f$ voltage noise. Evaluating the QPS terms S_{Ω}^r and S_{Ω}^a we observe that the latter scales linearly with the wire length L whereas the former does not. Hence, the term S_{Ω}^r can be safely neglected in the long wire limit. For the remaining QPS term S_{Ω}^a we get

$$S_{\Omega}^a = \frac{L\lambda^2 v_{\text{qps}}^2}{4e^2} \left[\zeta\left(\frac{\Phi_0 I}{2} - \Omega\right) - \zeta\left(\frac{\Phi_0 I}{2} + \Omega\right) \right] \times \frac{\sinh\left(\frac{\Phi_0 I}{2T}\right) \zeta\left(\frac{\Phi_0 I}{2}\right)}{((\Omega/2E_C)^2 + (\lambda/\pi)^2) \sinh\left(\frac{\Omega}{2T}\right)}. \quad (40)$$

At $T \rightarrow 0$ from Eq. (40) we find

$$S_{\Omega}^a \propto \begin{cases} I^{\lambda-1} (I - 2\Omega/\Phi_0)^{\lambda-1}, & \Omega < \Phi_0 I/2, \\ 0, & \Omega > \Phi_0 I/2. \end{cases} \quad (41)$$

In order to interpret this result we note that at $T=0$ each QPS event excites (at least) two plasmons with total energy $E = \Phi_0 I$ propagating in the opposite directions along the wire. One of those plasmons (with energy $E/2$) gets dissipated at the grounded end of the wire while another one (also with energy $E/2$) reaches its opposite end causing voltage fluctuations (emits a photon) with frequency Ω measured by a detector. Obviously, at $T=0$ this process is only possible at $\Omega < E/2$ in the agreement with Eq. (41).

In order to complete our analysis of voltage fluctuations we remark that Eqs. (30)–(32) allow to also recover all higher order correlators (cumulants) of the voltage operator, thus enabling one to construct full counting statistics of quantum phase slips. In the zero frequency limit this statistics is Poissonian, and it becomes very complicated beyond this limit.

To conclude, already in the “superconducting” regime $\lambda > 2$ the nanowires exhibit physical properties dramatically different from those of bulk superconductors. Such unusual behavior includes not only non-vanishing resistance of superconducting nanowires down to $T=0$ but also coherent voltage fluctuations generated by quantum phase slips. In the presence of a current bias I quantum tunneling of magnetic fluxons across the wire causes Poissonian shot noise with a non-trivial power law dependence of its spectrum on both I and frequency Ω .

“Insulating” regime: Localization of Cooper pairs

Let us now turn to the analysis of quantum fluctuations in superconducting nanowires in the “insulating” regime $\lambda < 2$. For simplicity we start by considering two somewhat different configurations displayed in Fig. 4. One of them (left plot) corresponds to a nanowire in the form of a ring with a perimeter $L = 2\pi R$. For brevity in what follows we will denote it as a QPS ring meaning that

Fig. 4 Left: Quantum phase slip ring, i.e., an ultrathin superconducting ring threaded by an external magnetic flux. Right: Quantum phase slip junction embedded in a thick superconducting ring. Reproduced from Semenov AG and Zaikin AD (2013) Persistent currents in quantum phase slip rings. *Physical Review B* 88: 054505.

the nanowire remains thin enough for QPS effects to be pronounced there. Another configuration (right plot) also corresponds to a superconducting ring which now has thicker and thinner parts. Quantum fluctuations of the order parameter are negligible in the bulk part of the ring but proliferate inside its thinner part (a nanowire of length L) which we will call a QPS junction. In both cases the superconducting ring is pierced by an external magnetic flux Φ_x .

For the sake of definiteness below we will only consider the case of a QPS ring, exactly the same results will also apply to a QPS junction. We first assume that the QPS ring perimeter L is small enough enabling us to disregard the coordinate dependence of our fluctuating variables of interest. Specifically, it implies that we can ignore the last term in the Hamiltonian (24). In this limit the effective Hamiltonian of our QPS ring that follows from Eqs. (24) and (25) takes the form.

$$\hat{H} = \frac{E_C}{2} (\hat{\phi} - \phi_x)^2 - \gamma_{\text{qps}} L \cos \hat{\lambda}, \quad (42)$$

where $E_C \sim g_\xi \Delta \xi / L$, $\hat{\phi} = \hat{\Phi} / \Phi_0$ and $\phi_x = \Phi_x / \Phi_0$.

The Hamiltonian (42) describes a fictitious quantum particle on a ring in the presence of a cosine external potential. The solution of this problem is well known from any standard course in quantum mechanics. One can distinguish two different regimes by comparing the “kinetic” and “potential” energies E_C and $\gamma_{\text{qps}} L$ or, equivalently, by comparing the ring perimeter L and the parameter (Zaikin, 2010)

$$L_{c0} \sim \xi \exp(ag_\xi/2). \quad (43)$$

For smaller rings with $L \ll L_c$ the flux-dependent ground state energy of the problem reads $E_0(\phi_x) \simeq (E_C/2) \min_n (n + \phi_x)^2$ except in the vicinity of the crossing points $\phi_x = 1/2 + n$ where the gap to the first excited energy band $\delta E_{01} = \gamma_{\text{qps}} L$ opens up due to level repulsion. Evaluating the supercurrent I flowing around the ring at $T \rightarrow 0$ by means of the formula

$$I = \frac{e}{\pi} \frac{\partial E_0(\phi_x)}{\partial \phi_x}, \quad (44)$$

one recovers the standard sawtooth-like dependence which—not too close to the points $\phi_x = 1/2 + n$ —is not affected by QPS.

For larger ring perimeters $L \gtrsim L_{c0}$ the bandwidth shrinks while the gaps become bigger. Then, combining the corresponding solution for the ground state energy $E_0(\phi_x)$ with Eq. (44), at $T \rightarrow 0$ we obtain

$$I = I_0 \sin(2\pi\phi_x), \quad I_0 \sim e g_\xi \Delta \sqrt{\frac{L}{\xi}} e^{-\frac{3ag_\xi}{4\xi}} e^{-L/L_{c0}}. \quad (45)$$

This equation demonstrates that quantum phase slips yield exponential suppression of the supercurrent even at $T = 0$ provided the ring perimeter L exceeds the critical value L_{c0} (43).

As we already pointed out, the above analysis holds only for sufficiently small values of the ring perimeter L . In a general case it is necessary to employ the full sine/Gordon Hamiltonian (24), (25) instead of the reduced one (42). This amounts to taking into account logarithmic interactions between quantum phase slips, cf., e.g., Eq. (17). This task can be accomplished by means of the RG approach employing (19).

As before, assuming for simplicity that $v/\Delta x_0 \sim \xi$ and starting renormalization at the shortest scale $\Lambda \sim \xi$ we proceed to bigger scales. Ignoring weak renormalization of the parameter λ we obtain the solution of Eq. (19) in the form $\gamma_{\text{qps}}(\Lambda) = \gamma_{\text{qps}}(\xi/\Lambda)^\lambda$. Our RG procedure should be stopped at the scale corresponding to the ring perimeter $\Lambda \sim L$. As a result, we arrive at the renormalized QPS amplitude

$$\tilde{\gamma}_{\text{qps}} = \gamma_{\text{qps}}(\xi_c/L)^\lambda. \quad (46)$$

This result allows to conclude that inter-QPS interaction effects remain weak and can be disregarded only for very small values of $\lambda \ll 1/\ln(L/\xi)$ or, equivalently, for ring perimeters obeying the inequality

$$L \ll \xi \exp\left(\frac{1}{\lambda}\right). \quad (47)$$

This inequality naturally restricts both the wire length and cross section values at which it can be treated as a zero-dimensional object described by the Hamiltonian (42).

Substituting the renormalized QPS amplitude (46) instead of the bare one and extracting the correlation length L_c from the condition $E_C \sim \tilde{\gamma}_{\text{qps}} L$, we get (Semenov and Zaikin, 2022)

$$L_c \sim \xi \exp\left(\frac{ag_\xi}{2-\lambda}\right), \quad (48)$$

where λ is supposed not to exceed 2. We observe that the correlation length L_c (48) increases with increasing λ and eventually diverges at the quantum phase transition point $\lambda = 2$. In the limit of small $\lambda \ll 1/\ln(L/\xi)$ the parameter L_c reduces to L_{c0} (43).

As before, for smaller rings with $L \ll L_c$ and at $T \rightarrow 0$ the supercurrent I is almost insensitive to QPS, whereas in the opposite limit $L \gg L_c$ we again reproduce Eq. (45) for I , where now

Fig. 5 Localization of Cooper pairs in the ground state of a uniform superconducting nanowire due to strong zero-point fluctuations of magnetic flux. Reproduced from Arutyunov KYu, Lehtinen JS, Radkevich A, Semenov AG, and Zaikin AD (2021) Superconducting insulators and localization of Cooper pairs. *Communications Physics* 4: 146. This work is licensed under a Creative Commons Attribution 4.0 International License, <http://creativecommons.org/licenses/by/4.0/>.

$$I_0 \sim eg_\xi \Delta \left(\frac{R}{\xi} \right)^{1/2-3\lambda/4} e^{-\frac{3g_\xi}{4} e^{-\frac{1}{\gamma_{\text{QPS}}^2}}} e^{-(L/L_c)^{1-1/2}}. \quad (49)$$

We observe that the supercurrent gets essentially suppressed by quantum fluctuations as soon as L exceeds L_c .

The same conclusions hold also for superconducting nanowires displayed, e.g., in Fig. 3. For such wires we again apply the sine-Gordon Hamiltonian (24), (25) but, unlike in the case of a ring geometry of Fig. 4, we do not anymore impose any periodic boundary conditions at the wire ends. It is well established that for $\lambda < 2$ the relevant excitations of our sine-Gordon theory are kinks and anti-kinks (as well as their bound states) with an effective gap in the spectrum $\tilde{\Delta} \propto \gamma_{\text{QPS}}^{2-2\lambda}$. This gap, in turn, gives rise to the same correlation length $L_c \propto 1/\tilde{\Delta}$ defined in Eq. (48).

The appearance of this fundamental length scale in our problem is directly related to the flux-charge duality. It can be interpreted as a result of spontaneous tunneling of magnetic fluxons Φ_0 back and forth across the wire, as it is illustrated in Fig. 5. These strong quantum fluctuations of magnetic flux wipe out phase coherence at distances $\geq L_c$ and yield effective *localization of Cooper pairs* at such length scales. Accordingly, one may interpret the energy $\sim \xi \Delta g_\xi / L_c \propto \tilde{\Delta}$ as an effective Coulomb gap for the wire segment of length $\sim L_c$.

To conclude, the properties of the “insulating” phase realized at $T \rightarrow 0$ in thinnest wires and rings with $\lambda < 2$ turn out to be highly non-trivial. In this phase, quantum phase slips remain unbound and determine a nonperturbative localization length of Cooper pairs L_c beyond which the supercurrent gets suppressed by quantum fluctuations. Accordingly, for $T \rightarrow 0$ such nanowires turn insulating only at length scales exceeding L_c , whereas at shorter length scales they may still exhibit superconducting properties.

Conclusion

In a sharp contrast to bulk superconductors, low temperature properties of quasi-one-dimensional nanowires are essentially determined by quantum fluctuations which are, in turn, controlled by two different parameters, the dimensionless normal state conductance of the wire segment g_ξ and the dimensionless wire admittance g_Z . Both these parameters (1) decrease with decreasing wire diameter, thus making quantum fluctuations progressively more pronounced.

Provided g_ξ remains very large, the low temperature behavior of the system is determined by small (Gaussian) quantum fluctuations of the phase of the order parameter controlled by the parameter g_Z . Such fluctuations are directly related to sound-like plasma modes propagating along superconducting nanowires. As soon as the dimensionless conductance g_ξ becomes not too large quantum phase slips come into play forming a logarithmically interacting “gas” in $1 + 1$ (space + time) dimensions. Such interactions between different QPS are mediated by plasma modes and cause a “superconductor-insulator” quantum phase transition at $T \rightarrow 0$ and $\lambda \equiv g_Z/8 \simeq 2$.

The “superconducting” phase $\lambda > 2$ is characterized by bound QPS pairs and weaker decay of superconducting correlations in space-time. Nevertheless, even in this regime current-biased superconducting nanowires acquire a non-zero resistance and exhibit shot noise of the voltage. These phenomena can be interpreted in terms of tunneling of quantum fluxons across the nanowire. In the context of flux-charge duality, such fluxons (“charged” by the flux quantum Φ_0) can be treated as effective quantum “particles” exactly dual to Cooper pairs with charge $2e$. Such “particles” obey complicated full counting statistics which reduces to Poissonian one in the zero frequency limit.

In thinner nanowires with $\lambda < 2$ quantum phase slips remain unbound and superconducting correlations decay exponentially at length scales exceeding the size of a “superconducting domain” $\sim L_c$ (48). At such length scales and at $T \rightarrow 0$ superconducting

nanowires exhibit an insulating behavior, whereas at shorter length scales they may demonstrate superconducting properties albeit possibly affected by quantum fluctuations of the phase. Hence, the correlation length L_c may be interpreted as an effective *localization length for Cooper pairs*.

These and other non-trivial quantum properties of superconducting nanowires remain under intensive investigation and also form a basis for a variety of applications of such nanowires in quantum information technology, metrology and nanoelectronics.

Abstract

This chapter presents an overview of the physics of superconductor-ferromagnet (S/F) hybrid structures. In addition to the important role in the development of superconducting spintronics, topological superconductors, and radiation detectors, these structures present a variety of exciting effects resulting from the interaction between superconductivity and magnetism. The superconducting proximity effect produces an oscillatory electron pair wave function inside the ferromagnet. This has several striking consequences, such as non-monotonic dependence of the critical temperature on the thickness of the ferromagnet and the “ π ” Josephson effect. Moreover, an odd-frequency triplet component of the superconducting condensate is generated in such systems. Since it is also even in momentum, the triplet is insensitive to non-magnetic disorder. When the magnetization of the ferromagnet is non-homogeneous, the triplets can penetrate over large distances in a ferromagnet even with a strong exchange field. We also discuss the inverse proximity effect in S/F structures, which induces a finite magnetic moment in the superconductor and may lead to spin-splitting of the density of states. We finish the chapter with an overview of the non-equilibrium properties of S/F structures.

Key points

- The superconductor/ferromagnet (S/F) structures provide a platform to explore the interplay and coexistence of two antagonistic phenomena - ferromagnetism and superconductivity.
- The proximity effect at the S/F interface produces an oscillatory electron-pair wave-function inside the ferromagnet. This leads to several striking phenomena, such as non-monotonic dependence of the critical temperature on the thickness of the ferromagnet, and the “ π ” Josephson effect.
- An odd-frequency triplet component of the superconducting condensate is generated in S/F structures. Since it is also even in momentum, the triplet is insensitive to non-magnetic disorder. In the case when magnetization of the ferromagnet is non-homogeneous, the triplets can penetrate across large distances in the ferromagnet and are not suppressed even by strong exchange fields.
- Magnetism may be induced in a superconductor in a S/F structure - the magnetic proximity effect. This manifests as suppression of the critical temperature and the spin-splitting of the density of states of the superconductor.
- S/F structures also provide a good platform to explore novel non-equilibrium phenomena related to the coupling of different electronic degrees of freedom.

Introduction

The interplay between superconductivity and exchange fields has been a topic of interest practically since the publication of the BCS theory in 1957. In a very early work, [Abrikosov and Gor'kov \(1960\)](#) demonstrated how a small amount of random magnetic impurities suppresses superconductivity, by breaking the local time-inversion symmetry due to the exchange field between impurities and conduction electrons. If the impurities are ferromagnetically aligned the situation is even more detrimental for conventional superconductivity, since the effective exchange field generated by the impurities tries to align the spins of the Cooper pair, which are in a singlet state. This leads to a pair-breaking mechanisms and hence suppression of the superconducting state.

An interesting consequence of the interplay between superconductivity and an exchange field was predicted separately by Fulde and Ferrell (1964) and Larkin and Ovchinnikov (1965), who showed that the exchange field in a superconductor can lead to an inhomogeneous superconducting state, the so called FFLO state. This state is very sensitive to disorder and therefore very difficult to observe in conventional superconductors.

There is, however, another platform that allows the study of the interplay between superconductivity and exchange fields at the mesoscopic scale: the hybrid superconductor/ferromagnet S/F structures, which show interesting emerging states. In the case of S/F metallic structures, the superconducting *proximity effect* allows superconducting pair correlations to penetrate into the ferromagnet, in analogy to the proximity effect in superconductor/normal metal systems. The difference with the latter is that the electrons of the pair, which in conventional superconductors are in a singlet state, in the ferromagnet experience a different potential depending on their spin. This means that at the Fermi level, each electron in the pair acquires a different momentum, and the total momentum of the pair is no longer zero. Quantitatively, in an ideal 1D case, the momentum at the Fermi level for spin-up (down) electrons is $p_{\pm} = p_F \pm h/v_F$, where h is the exchange field in the ferromagnet, and v_F and p_F are the Fermi velocity and momentum, respectively. Thus, the total momentum acquired by the electron pair is $Q \equiv p_+ - p_- = 2h/v_F$, which determines the oscillation period of the superconducting correlations in the ferromagnet, in a sense analogous to the FFLO state.

In real metallic S/F structures, the oscillations of the superconducting correlations in the F layer is accompanied by an exponential decay away from the S/F interface. Specifically, the electron pair wave function has the form

$$\Psi(x) \sim e^{-x/\xi_F}, \quad (1)$$

where x is the spatial coordinate normal to the S/F interface and ξ_F is a complex length defined in a metallic system by

$$\xi_F \sim \sqrt{\frac{D_F}{2(\pi T + i\hbar)}}. \quad (2)$$

Here D_F is the diffusion coefficient of the F metal, T the temperature, and we use the units where $\hbar = k_B = 1$. In a non-magnetic metal (N), $h = 0$ and the decay of Ψ into N is over the thermal length $\sim \sqrt{D_N/T}$, which at low temperature is only limited by inelastic scattering [see Fig. 1A].

In a ferromagnet h is finite and the pair correlation function oscillates and decays in space according to Eqs. (1), (2), see Fig. 1B. This results in a several remarkable phenomena discussed in detail in Section “Metallic S/F structures”: non-monotonic dependence of the critical temperature on the thickness of the F layers in S/F bilayers, oscillation of the local electronic density of states in S/F bilayers, and a phase shift of π in the current-phase relation of a S/F/S Josephson junctions, for certain thicknesses of the F-layer.

Metallic S/F structures

Most of the experimental research on S/F structures is done on metallic systems. Typical superconductors are Al, Nb, V, whereas F layers consist of Fe, Ni, Co, Py, Ho, etc. All these materials can be well described using the diffusion equation, which in the case of superconductivity was derived by Usadel (1970). For a qualitative description of the proximity effect and calculation of observables, such as the critical current or the density of states, it is most often sufficient to consider the linearized Usadel equation. It is an equation determining the anomalous quasiclassical Green's function, $\hat{f}$, describing the superconducting pair condensate in the F layer:

$$-D_F \nabla^2 \hat{f} + \left\{ |\omega_n| + i\mathbf{h} \cdot \boldsymbol{\sigma} \text{sgn} \omega_n, \hat{f} \right\} = 0. \quad (3)$$

Here $\omega_n = \pi T(2n + 1)$ are the Matsubara frequencies, $\mathbf{h}$ the exchange field in the ferromagnet, and $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ is the vector of spin Pauli matrices. The condensate function depends on the spatial coordinate and the frequency, $\hat{f}(\mathbf{r}, \omega_n)$, and it is a matrix in spin space. Eq. (3) is valid when superconducting correlations in F are weak, which is true at large temperatures $T \gg \Delta$, as well as for the case of a weak proximity effect due to non-ideal S/F interfaces. If these conditions are not met, the non-linear Usadel equation must be used.

In order to determine the function $\hat{f}$, Eq. (3) needs to be supplemented with a boundary condition at the S/F interface

$$\partial_x \hat{f} = -\gamma \hat{f}_{BCS}. \quad (4)$$

Here, γ is a parameter describing the transparency of the interface ($\gamma = 0$ corresponds to infinitely resistive interface, whereas $\gamma \rightarrow \infty$ describes a fully transparent interface), x is the direction perpendicular to the interface, and $\hat{f}_{BCS} = \Delta / \sqrt{\omega_n^2 + \Delta^2}$.

One can solve Eq. (3) for the case of an homogeneous magnetization and a very long F layer ($d_F \gg \xi_F$), where we set $\mathbf{h} \cdot \boldsymbol{\sigma} = h\sigma_z$ without loss of generality. $\hat{f}$ is then a diagonal matrix with elements

$$f_{\pm} = \gamma \hat{f}_{BCS} \xi_{\pm} e^{-x\xi_{\pm}/|\xi_{\pm}|^2} e^{ix\xi_{\pm}/|\xi_{\pm}|^2}, \quad (5)$$

where $\xi_{\pm} = \sqrt{D_F/(2|\omega_n| \mp 2ih\text{sgn}\omega_n)} = \xi_r \pm i\text{sgn}\omega_n \xi_i$, and

Fig. 1 Schematic representation of the spatial dependence of the pair correlation function Ψ in a (A) S/N structure, (B) S/F structure with homogeneous magnetization, and (C) S/F structure with inhomogeneous magnetization. In panel (C) SRT and LRT stand for short-range and long-range triplets, respectively.

$$\xi_{r,i} = \sqrt{D_F \frac{\sqrt{|\omega_n|^2 + h^2} \pm |\omega_n|^2}{4(|\omega_n|^2 + h^2)}}. \quad (6)$$

Eq. (5) confirms the decay and oscillations of the condensate function in the F layer. For a strong ferromagnet with $h \gg \Delta$, the decaying length and oscillation period is $\xi_F \sim \sqrt{D_F/h}$, which for usual ferromagnets (Fe, Co) corresponds to a sub-nanometer scale. This length scale is too short to be probed in an experiment, and therefore, one needs to use weaker ferromagnets with $h \lesssim \Delta$, or as we discuss below, to create pair correlations with equal spin projection.

Manifestations of oscillatory condensate function in observables

The oscillations of the condensate function in the ferromagnet lead to several theoretical predictions successfully tested in experiments. For example, the critical temperature T_c of the S/F bilayer shows non-monotonic behavior as a function of the thickness d_F of the ferromagnetic layer (Buzdin and Kupriyanov, 1990; Radović et al., 1991). Furthermore, T_c can be calculated by combining the solution of the linearized Usadel equation with the self-consistency condition for the order parameter Δ . Fig. 2A shows the measurement of T_c by Lazar et al. (2000), which is in good agreement with theoretical predictions.

Fig. 2 Main results of several experiments on S/F structures. (A) Measurement of non-monotonic critical temperature in Pb/Fe bilayers as a function of ferromagnet thickness d_F . The solid and dashed lines are fits to the theory assuming a perfect and imperfect interface, respectively. (B) Measurements of the differential conductance in PdNi/Nb bilayer for different thicknesses of the ferromagnet PdNi, illustrating oscillating density of states. (C) Critical current of a S/F/S Josephson junction as a function of the thickness of the ferromagnet PdNi. The point where critical current vanishes ($d_F \sim 65$ Å) corresponds to the transition from “0” to “ π ” phase. Another example are the oscillations of the local quasi-particle density of states (DoS) $N(\epsilon)$ (Buzdin, 2000), which can be calculated using Eq. (5) as $N(\epsilon) = N_0 + \delta N(\epsilon)$, where

$$\delta N(\epsilon) = \frac{N_0}{4} \text{Re}(f_+^2 + f_-^2) \Big|_{i\omega_n \rightarrow \epsilon}. \quad (7)$$

Here, N_0 is the DoS in the normal state of the F layer, δN is the correction due to the superconducting proximity effect, and ϵ is the energy. In S/N structures, induced superconductivity suppresses the density of states around the Fermi level, $\epsilon = 0$. In other words, $\delta N < 0$. If one goes beyond the linearized limit, such suppression can be significant and induce a gap in the density of states of the N layer. In contrast, the spatial oscillations of the condensate in S/F structures can lead to different signs of δN , and hence to a situation where the DoS of S/F is *higher* than F alone at $\epsilon = 0$ for some d_F . This has been seen in the tunneling spectroscopy experiment by Kontos et al. (2001) [see Fig. 2B].

The oscillations of the superconducting condensate also manifest in the Josephson effect of S/F/S junctions. The Josephson effect establishes that the supercurrent can flow in the junction of two superconductors in the presence of a phase difference φ between them

$$I_S = I_c \sin \varphi. \quad (8)$$

Eq. (8) is known as the current-phase relation, where I_c is the critical current of the junction. The ground state of the junction corresponds to a zero-current state, which is either at $\varphi = 0$ or $\varphi = \pi$. In conventional tunneling or S/N/S Josephson junctions, $\varphi = 0$ corresponds to a minimum of energy; therefore, it is the ground state of the junction. Moreover, in an S/N/S junction, I_c monotonically decreases as the N thickness increases. In a S/F/S junction, because of the oscillation of the condensate function, I_c has an oscillatory behavior. In the case of large exchange field $h \gg T$ and large temperatures the critical current is given by

$$I_c \sim e^{-d_F/\xi_F} \cos(d_F/\xi_F), \quad (9)$$

where $\xi_F \sim \sqrt{D_F/\hbar}$. Therefore, depending on the thickness d_F , I_c may change its sign. If $I_c < 0$, then $\varphi = 0$ corresponds to a maximum of the Josephson energy, which is now minimized by $\varphi = \pi$. Junctions with positive and negative I_c are called “0” and “ π ” junctions, respectively. The “0- π ” transition in S/F/S junctions was first predicted by Buzdin, Bulaevskii, and Panyukov in 1982 (Buzdin, 2005; Buzdin et al., 1982) and observed in several experiments (see e.g. Ryazanov et al. (2001), Kontos et al., (2002)). In the former experiment, a ferromagnet $\text{Cu}_x\text{Ni}_{1-x}$ has been used, whose exchange field is weak, $h \sim T_c$. In this case, the penetration of the condensate function in the F region is long-range. The complex length ξ_+ depends on temperature and leads to oscillations of I_c as a function of the temperature, as observed in the experiment. Oscillations of I_c as a function of d_F have also been reported in experiments [see Fig. 2C].

Odd-frequency triplet superconductivity in S/F structures

In 2001, the same year that the 0- π transition was experimentally verified, Bergeret, Volkov, and Efetov (Bergeret et al., 2001, 2005; Kadigrobov et al., 2001) predicted the existence of a long-range triplet component of the superconducting condensate in S/F structures with inhomogeneous magnetization. Such component corresponds to equal-spin Cooper pairs, which are insensitive to the exchange field. To understand how this component appears it is sufficient to consider the linearized theory of the previous section.

If the magnetization is homogeneous there is a single spin quantization axis, and the condensate matrix $\hat{f}$ is diagonal with components $f_{\pm}$, see Eq. (5). If the magnetization of the F layer is inhomogeneous, for instance due to magnetic domains and domain walls, the condensate matrix can be decomposed into singlet and triplet components:

$$\hat{f} = f_s \sigma_0 + \mathbf{f}_t \cdot \boldsymbol{\sigma}, \quad (10)$$

where $\mathbf{f}_t = (f_x, f_y, f_z)$ is the triplet condensate vector. In the previous example of a homogeneously magnetized ferromagnet, only the singlet and f_z component are finite, with $f_s = (f_+ + f_-)/2$ and $f_z = (f_+ - f_-)/2$. The latter corresponds to the triplet component with zero total spin projection, i.e. to the Cooper pair state ($\uparrow\downarrow + \downarrow\uparrow$).

It follows from Eq. (3) that:

- (i) The exchange field term always leads to singlet-triplet conversion.
- (ii) The singlet component is an even function of the Matsubara frequency, whereas the triplet component is odd in frequency. This is a consequence of the Pauli exclusion principle. Namely, the components of $\mathbf{f}_t$ are even in momentum (*s*-wave symmetry) and even in spin (triplet state), and therefore they need to be odd in frequency. This type of superconductivity is denoted as odd-frequency triplet superconductivity.
- (iii) Since these odd-frequency triplets are even in momentum, they are insensitive to non-magnetic disorder (Anderson theorem). This is in contrast to triplets associated with unconventional superconductivity with *p*-wave symmetry, which are suppressed by disorder.
- (iv) Components of the triplet vector $\mathbf{f}_t$ orthogonal to the local exchange field $\mathbf{h}$ are not affected by it. Namely, those components decay in F without oscillating, over the thermal length $\xi_T = \sqrt{D_F/(2|\omega_n|)}$. In a ferromagnet with a strong exchange field, ξ_T is much larger than the magnetic length defined in Eq. (5). Thus, this component is long-range [see the sketch in Fig. 1C].

Long-range triplets correspond to Cooper pairs in a triplet state with finite spin projection, i.e. combination of ($\uparrow\uparrow$) and ($\downarrow\downarrow$). Because the spins of the electron pairs are parallel, they induce spin-polarized supercurrents in a S/F/S junction.

Observation of long-range Josephson coupling attributed to triplet supercurrents has been reported in a wide variety of magnetic materials, including half-metals (Keizer et al., 2006; Singh et al., 2015), multilayered F-structure (Khaire et al., 2010), and magnets with conical magnetic texture such as Ho (Robinson et al., 2010).

The role of spin-orbit coupling

The physical picture described above may be modified in an S/F system with spin-orbit coupling (SOC). Namely, SOC in diffusive systems leads to spin relaxation, which in the superconducting state manifests as an additional relaxation of the triplet component of the condensate. Specifically, the characteristic length over which the long-range triplet component of the condensate decays in a ferromagnet is given by (Demler et al., 1997)

$$\xi_t^{-1} = \sqrt{\frac{2}{D_F} \left(|\omega_n| + \frac{4}{\tau_{so}} \right)}, \quad (11)$$

where τ_{so} is the scattering time between collisions at spin-orbit impurities.

In S/F systems with a lack of inversion symmetry, due to either non-centrosymmetric materials, or hybrid interfaces, SOC can be of the Rashba type. In such a case the effect of SOC can be introduced in the diffusion equation, Eq. (3), as a SU(2) vector potential, $\hat{A}$, by substituting the derivatives by SU(2)-covariant ones: $\nabla \rightarrow \tilde{\nabla} = \nabla - i[\hat{A}, \cdot]$. This substitution leads to new terms describing precession and relaxation of the triplet component. In particular, the precession term may convert the short-range triplet component into a long-range one. Moreover, Rashba-like SOC in superconducting structures may lead to an additional source of singlet-triplet conversion.

The SOC-mediated singlet-triplet conversion in combination with a finite magnetization leads to a variety of magnetoelectric phenomena in S/F structures, meaning that a spin response can be achieved by passing a current and vice-versa. Some prominent examples of such phenomena are the anomalous Josephson effect, where an arbitrary phase shift φ_0 can appear in the current-phase relation, and the supercurrent diode effect, where the critical current depends on the direction of current flow.

Magnetic proximity effect

While the superconducting proximity effect is responsible for the effects described above, the inverse proximity effect, or magnetic effect, is also important. Namely, magnetism may be induced in a superconductor in an S/F structure. The first manifestation of this phenomenon is the strong suppression of the superconducting critical temperature of thin S films in contact with F metal with a strong exchange field. However, superconductivity survives if the superconductor is thick enough or the exchange field is not particularly strong. The triplet correlations induced in the F layer may penetrate the S layer and change its spectrum. Indeed, as predicted by Bergeret et al. (2004) and verified experimentally by Xia et al. (2009), the triplet correlations induce a magnetic moment in the superconductor opposite to the average magnetization of the itinerant electrons in the ferromagnet. For example, the magnetic moment of an F particle embedded in a superconductor is screened via the inverse proximity effect, as illustrated in Fig. 3.

Such screening can be understood by recalling the paramagnetic response of a superconductor. In the pure paramagnetic case a magnetic field B induces in a superconductor a magnetic moment:

Fig. 3 Ferromagnetic grain embedded in a superconductor. The magnetic moment of the grain is screened by the superconductor due to the magnetic proximity effect.

$$\mathbf{S} = \chi_0 \mathbf{B} + \delta \mathbf{S}(T). \quad (12)$$

The first term is the usual Pauli paramagnetic term, with $\chi_0 = -2\mu_B N_0$ and μ_B being the Bohr magneton. The second term is the deviation from the Pauli paramagnetic response due to the superconducting correlations. In a homogeneous case and at zero temperature $\delta \mathbf{S}(T) = -\chi_0 \mathbf{B}$, which reflects the fact that superconductors exhibit zero paramagnetic response at $T = 0$. In the presence of SOC $\delta \mathbf{S}(0) \neq -\chi_0 \mathbf{B}$, and the superconductor may exhibit a finite paramagnetic susceptibility at $T = 0$.

In a hybrid S/F structure, the ferromagnet is usually described by free electrons in an effective exchange field $\mathbf{h}$ acting as a paramagnetic field. It is only finite in the F region and induces a local magnetic moment equivalent to the Pauli term in Eq. (12), proportional to $N_0 \mathbf{h}(\mathbf{r})$. The second term on the right-hand side of Eq. (12) describes the response of the superconductor to the exchange field. It is a non-local magnetic moment with an opposite sign extending over a distance of the order of the superconducting coherence length away from the F region (see Fig. 3). While the local magnetic moment is finite, after spatial integration, the total one is zero at $T = 0$, as in the homogeneous case. The local magnetic moment can be probed using the polar Kerr effect or low-energy muons.

Superconductor-ferromagnetic insulator structures

Beside all-metallic S/F structures, the magnetic proximity effect can also be observed in ferromagnetic insulator/superconductor structures (FI/S) (Hijano et al., 2021; Meserve and Tedrow, 1994). Ferromagnetic insulators, such as EuS, EuO, or GdN, when put in contact with a thin superconducting film, such as Al or Nb, may induce in the latter a spin-split BCS density of states. This is equivalent to the Zeeman splitting induced in a thin superconducting film in a large in-plane magnetic field [see Fig. 4A]. At the same time, since the electrons from S cannot penetrate the insulating FI, there is no superconducting proximity effect. In other

Fig. 4 (A) Spin-split density of states in a FI/S structure. (B) Measurements of the differential conductance of a EuS/Al structure, as a function of externally applied magnetic field B and voltage, from Hijano et al., (2021). Well defined spin-splitting can be observed even at $B = 0$. Adapted from Hijano A, Ilić S, Rouco M, González-Orellana C, Ilyn M, Rogero C, Virtanen P, Heikkilä T, Khorshidian S, Spies M. et al. (2021) Coexistence of superconductivity and spin-splitting fields in superconductor/ferromagnetic insulator bilayers of arbitrary thickness. *Physical Review Research* 3(2): 023131. This work is licensed under a Creative Commons Attribution 4.0 International License, <http://creativecommons.org/licenses/by/4.0/>.

words, the Cooper pairs do not “leak” from S to FI, resulting in robust superconductivity in S and sharp coherence peaks in the density of states.

The origin of spin-splitting is the interfacial effective exchange coupling between the localized magnetic moments of the FI and the conduction electrons of the S layer. If the thickness of the latter is smaller than the coherence length, then the density of states can be assumed to be homogeneous in space and given by $N(\epsilon) = \frac{1}{2} [N_{\uparrow}(\epsilon) + N_{\downarrow}(\epsilon)]$, with

$$N_{\uparrow,\downarrow}(\epsilon) = \text{Re} \frac{\epsilon \pm h_{\text{eff}}}{\sqrt{(\epsilon \pm h_{\text{eff}})^2 - \Delta^2}}, \quad (13)$$

where $N_{\uparrow,\downarrow}$ is the density of states for spin-up and -down. The effective spin-splitting field h_{eff} is given by the interfacial exchange field multiplied by a/d_S , where a is an atomic length scale over which the exchange interaction takes place, and d_S the thickness of the superconducting layer.

Since the end of the 1980s, numerous spectroscopy experiments on EuS/Al have demonstrated large spin-split density of states even at zero magnetic field [see Fig. 4]. Recently, interest in these systems has been renewed because of their potential for application in detectors, spintronics, and topological superconducting qubits.

For some of these applications, an important feature of FI is that it can also act as a spin-filtering tunneling barrier, as spin-filtering combined with spin-splitting leads to electron-hole (e-h) symmetry breaking. Namely, the total DoS $N(\epsilon)$ is e-h symmetric, $N(\epsilon) = N(-\epsilon)$, however if one spin species is filtered-out the symmetry is broken, $N_{\uparrow,\downarrow}(\epsilon) \neq N_{\uparrow,\downarrow}(-\epsilon)$, as seen from Eq. (13). Such spin-dependent transport leads to several interesting phenomena in FI/S structures, such as thermoelectric effects and rectification of AC currents which can be used for detectors or thermometers.

F/S/F spin valves

Another manifestation of the magnetic proximity effect is the change of the critical temperature of F/S/F structures, called spin-valves, when the relative magnetization of the two F layers changes between parallel (P) and antiparallel (AP) configurations (see Fig. 5). The effective exchange field in the superconducting layer is an average of the exchange fields induced at each S/F interface. In the P configuration the averaged exchange field induced in the superconductor is larger as in the AP case, and therefore leads to lower critical temperature.

This behavior was theoretically predicted by De Gennes (1966) on the example of FI/S/FI structures and verified in experiments by Hauser (1969). In later works, these claims were extended to metallic samples: theoretically by Buzdin et al. (1999) and Tagirov (1999), and experimentally by Gu et al. (2002) and Moraru et al., (2006). Another type of spin valve, namely S/F/F/S junctions, has been used to accurately control the $0-\pi$ transition by Gingrich et al. (2016).

Non-equilibrium properties of S/F structures

So far we considered the spectral and equilibrium properties of S/F hybrid structures. There is also a large experimental and theoretical activity on the transport properties of such structures under non-equilibrium conditions (Beckmann, 2016; Bergeret et al., 2018; Heikkilä et al., 2019). A typical experimental setup is sketched in Fig. 6: a superconducting wire is contacted to various

Fig. 6 Sketch of a setup for detection of the non-equilibrium modes in a superconductor (blue wire) via transport measurements. Injector and detector are normal or ferromagnetic metals.

electrodes, which can be non-magnetic or ferromagnets. One can, for example, inject a current from the injector by applying a voltage V_{inj} , and measure the current I_{det} in the detector circuit at zero bias (Hübler et al., 2012). The injected current drives the superconductor to a nonequilibrium state. Then, the current in the detector is given by the expression

$$I_{det} = G_{det}(\mu + P_{det}\mu_s), \quad (14)$$

where G_{det} is the tunneling conductance and P_{det} is the effective spin polarization of the detector. The charge imbalance μ and spin accumulation μ_s are related to the different components of the distribution function matrix via [see Silaev et al., 2015]:

$$\mu = -\frac{1}{2} \int_0^\infty d\epsilon (N_+ F_T + N_- F_{Ls}), \quad (15)$$

$$\mu_s = -\frac{1}{2} \int_0^\infty d\epsilon [N_+ F_{Ts} + N_- (F_L - F_{eq})], \quad (16)$$

where $N_\pm = N_\uparrow \pm N_\downarrow$, and $F_{eq}(\epsilon) = \tanh(\epsilon/2T)$ is the equilibrium distribution function. The different functions F describe the different non-equilibrium modes. We use here the conventional notation denoting by the label T/L the transverse/longitudinal modes, which are symmetric/antisymmetric functions of the energy ϵ . F_T describes the charge imbalance mode, which quantifies the imbalance between quasiparticles above and below the Fermi surface. This mode can be excited by charge injection from a normal electrode to the superconductor. The mode F_L describes local changes in the effective temperature. Any heating mechanism can generally generate it. In the absence of ferromagnets, only these two modes can be excited and have been widely studied in the 70s and 80s. In the presence of ferromagnetic injectors/detectors, or spin-splitting fields in the superconductor, another two modes appear. The spin imbalance mode, F_{Ts} , describes the spin accumulation induced, for example, by a spin-polarized current injected from a ferromagnetic electrode. And finally the spin-energy mode, F_{Lj} , describes a non-equilibrium state with antisymmetric differences in the electron-hole and spin-up/down distributions. Nonequilibrium modes are determined by the Keldysh-Usadel kinetic equations presented in Silaev et al. (2015).

Fig. 7A shows the calculated non-local conductance defined as $g_{nl} = dI_{det}/dV_{inj}$ for different values of the spin-splitting field h . At zero field, only the terms proportional to N_+ in Eqs. (15) and (16) contribute to the detector current, Eq. (14). The contribution from the spin accumulation, Eq. (16), decays over the spin relaxation length. Therefore, if the distance between injector and detector is much larger than this length, the signal is dominated by the charge imbalance. This explains the almost symmetric signal, $g_{nl}(V_{inj}) \approx g_{nl}(-V_{inj})$, observed in experiments on charge imbalance (Hübler et al., 2012; Quay et al., 2013).

In the case of a finite spin-splitting field $N_- \neq 0$, so the second terms in Eqs. (15) and (16) also contribute to g_{nl} . If the spin-splitting is caused by an external magnetic field, the latter suppresses the charge imbalance via the orbital depairing effect. The non-local signal is then dominated by the energy mode F_L , the second term in Eq. (16). This results in almost antisymmetric $g_{nl}(V_{inj})$ curves, as shown in Fig. 7A. This contribution is independent of the elastic spin-dependent scattering, since the F_L mode relaxes only by inelastic scattering. At low temperatures, inelastic scattering becomes weak and therefore the spin accumulation can be long-range, as observed in experiments by Hübler et al. (2012), Wolf et al. (2013) and Quay et al. (2013). The comparison between theory and the experiment by Hübler et al. (2012), Fig. 7B, shows a very good agreement.

Interestingly, according to the theory one can also generate a spin accumulation even if the injector is a nonmagnetic metal. The simple injection of a current at voltages larger than the superconducting gap generates energy imbalance F_L . If the spin-splitting field is finite, a long-range contribution from the second term of Eq. (16) appears. This is also in accordance with the observations of Wolf et al. (2013). Long-range spin-dependent signals can have direct applications in the field of spintronics (Eschrig, 2011; Linder and Robinson, 2015).

Fig. 7 (A) Calculated non-local conductance for different values of the spin-splitting field. (B) Comparison between theory (red curve) and experiment of Hübler et al. (2012) (blue curve). Adapted with permission from Silaev M, Virtanen P, Bergeret F, and Heikkilä T (2015) Long-range spin accumulation from heat injection in mesoscopic superconductors with Zeeman splitting. *Physical Review Letters* 114(16): 167002. Copyright (2015) by the American Physical Society.

Finally, the spin-energy mode, F_{LS} , has been recently detected by Kuzmanović et al. (2020) in a setup as the one sketched in Fig. 6. The experiment did not use ferromagnetic materials and hence only the charge imbalance, Eq. (15), contributes to the non-local signal, Eq. (14). Using the kinetic theory developed by Silaev et al. (2015) and Heikkilä et al. (2019), Kuzmanović et al. (2020) could unambiguously identify the spin energy mode F_{LS} .

Conclusion

The S/F structures provide an opportunity to study the interplay and coexistence of two antagonistic phenomena - ferromagnetism and superconductivity. As such, they have been a subject of vigorous investigation in the last few decades, both on the experimental and theoretical front. In this chapter we summarized the main results of these efforts, using a simple diffusion-like Usadel equation to qualitatively illustrate the main points.

The interest in these structures persists to this day, as they have been identified as a building block for many applications ranging from superconducting spintronics, topological superconductivity, to radiation detectors. Recent advances in sample preparation even allow to build atomically thin S/F structures in Van der Waals heterostructures, using monolayer ferromagnets such as NiBr_2 .

Abstract

Some properties of the flux-line lattice in conventional and high- T_c superconductors are reviewed, with particular emphasis on phenomenological theories, nonlocal elasticity, irreversible magnetization curves, and influence of the specimen shape on the electromagnetic response.

Key points

- Main concepts and results of Ginzburg-Landau and London theories
- Description of vortex lattices in type-II superconductors within the Ginzburg Landau and London theories
- Elasticity of the vortex lattice in type-II superconductors

Introduction

After the discovery of superconductivity in 1912 by Heike Kamerlingh-Onnes in Leiden, it took almost 50 years until this fascinating phenomenon was understood microscopically, when in 1957 Bardeen, Cooper, and Schrieffer established their BCS theory. But long before this electron-pairing theory, there were powerful phenomenological theories which were able to explain most electromagnetic and thermodynamic observations on superconductors, and which are very useful today also (Brandt, 1995; De Gennes, 1966; Tinkham, 1975). The London theory, conceived by Fritz and Heinz London in 1935, is particularly useful for the description of the high- T_c superconductors, which were discovered in 1987 by Bednorz and Muller in Zurich. Perhaps the most useful and elegant phenomenological theory of superconductors was established by Vitalii Ginzburg and Lew Landau in 1951. The Ginzburg-Landau (GL) theory generalizes Landau's theory of second-order phase transitions to spatially varying charged systems in a magnetic field and should thus be applicable near the superconducting transition temperature T_c , but in many cases it yields a qualitatively correct behavior also at lower temperatures. The GL theory can be derived from the microscopic BCS theory, and it reduces to the London theory in situations when the GL function (the superconducting order parameter) has nearly constant magnitude. The theory of Ginzburg and Landau was also generalized to the cases of multiband and unconventional superconductors (Orlova et al., 2013; Sigrist and Ueda, 1991).

The GL theory has high predictive power. It predicts that superconductors can be of type-I (with positive energy of the wall between normal conducting and superconducting domains) or of type-II (with negative wall energy, pointing to an instability) and that superconductivity can be suppressed by a high magnetic field and by a high current density, namely, by the depairing current which breaks the Cooper pairs. Its most spectacular success was the prediction of spontaneous nucleation and penetration of magnetic vortices in type-II superconductors by Alexei Abrikosov in 1957. The properties of these Abrikosov vortices (or fluxons, flux lines, carrying one quantum of magnetic flux $\Phi_0 = h/2e = 2.07 \times 10^{-15} \text{Tm}^2$) and their motion and pinning by material inhomogeneities, are important topics both in research and in the practical application of superconductors. Most applications

require type-II superconductors with high critical magnetic fields and currents, but high loss-free supercurrents require that the vortices are pinned so that they cannot move under the action of this current and dissipate energy.

Ginzburg-Landau theory

The GL theory introduces a complex, spatially varying order parameter $\psi(\mathbf{r})$ in addition to the magnetic field $\mathbf{B}(\mathbf{r}) = \nabla \times \mathbf{A}(\mathbf{r})$ or vector potential $\mathbf{A}$. The GL function $\psi(\mathbf{r})$ later turned out to be proportional to the BCS energy-gap function $\Delta(\mathbf{r})$, and its square $|\psi(\mathbf{r})|^2$ to the density of Cooper pairs. It defines two characteristic lengths: the superconducting coherence length ξ sets the scale over which $\psi(\mathbf{r})$ can vary, while λ governs the variation of the magnetic field as in the London theory. Both λ and ξ diverge at the superconducting transition temperature T_c according to $\lambda \propto \xi \propto (T_c - T)^{-1/2}$, but their ratio, the GL parameter $\kappa = \lambda/\xi$, is nearly independent of the temperature T . The GL theory reduces to the London theory (which is valid down to $T = 0$) in the limit $\xi \ll \lambda$, which means constant magnitude $|\psi(\mathbf{r})| = \text{const}$ (except in the vortex cores, where ψ vanishes, see below). The GL equations are obtained by minimizing a free-energy functional $F\{\psi, \mathbf{A}\}$ with respect to the GL function $\psi(\mathbf{r})$ and the vector potential $\mathbf{A}(\mathbf{r})$. With the length unit λ and magnetic field unit $\sqrt{2}B_c$ ($B_c = \Phi_0/(\sqrt{8}\pi\xi\lambda)$ is thermodynamic critical field), the GL functional reads

$$F\{\Psi, \mathbf{A}\} = \frac{B_c^2}{\mu_0} \int_V \left[-|\Psi|^2 + \frac{1}{2}|\Psi|^4 + \left| \left(-\frac{i\nabla}{\kappa} - \mathbf{A} \right) \Psi \right|^2 + (\nabla \times \mathbf{A})^2 \right] d^3r. \quad (1)$$

Here the integral is over the volume V of the superconductor. The first two terms are the superconducting condensation energy, which is minimum when $|\psi|^2 = 1$. The third term is the energy cost of the spatial variation of ψ ; this gauge-invariant gradient also introduces $\mathbf{A}$ and thus the magnetic field. The last term is the magnetic energy density $B^2/2\mu_0$.

The GL functional and the resulting GL equations may be expressed in terms of the real-valued function $|\psi|$ and the gauge-invariant supervelocity $\nabla\varphi/\kappa - \mathbf{A}$, where $\varphi(r)$ is the phase of $\psi = |\psi| \exp(i\varphi)$. From the variation $\delta F/\delta\psi = 0$ follows the first GL equation determining the amplitude and phase of ψ . From the variation $\delta F/\delta\mathbf{A} = 0$ follows the supercurrent density $\mathbf{J} = \mu_0^{-1}\lambda^2[(\Phi_0/2\pi)\nabla\varphi - \mathbf{A}][|\psi|^2]$, which has to be supplemented by the Maxwell equation $\mathbf{J} = \mu_0^{-1}\text{curl curl } \mathbf{A}$ to obtain an equation for $\mathbf{A}$ or $\mathbf{J}$ alone. The minimization of F yields not only the functions $\psi(\mathbf{r})$ and $\mathbf{A}(\mathbf{r})$, but also the boundary condition that the current density and supervelocity do not have a component perpendicular to the free surface of the superconductor.

In an external field H_a , one has to minimize not the free energy F but the Gibbs free energy $G = F - \bar{B}H_a$, where $\bar{B}$ is the spatial average of the magnetic induction B in the superconductor. The condition $\partial G/\partial \bar{B} = 0$ yields the equilibrium field $H_a = \partial F/\partial \bar{B}$. In sufficiently low H_a , the superconductor expels the applied magnetic field completely, that is, one has $B = 0$ inside the superconductor (Meissner state). More precisely, the parallel applied field penetrates into a thin surface layer of thickness λ . In a superconductor filling the half space $x \geq 0$, one has $B(x) = \mu_0 H_a \exp(-x/\lambda)$. This screening of H_a is caused by a surface current of density $j(x) = (H_a/\lambda) \exp(-x/\lambda)$ flowing perpendicular to H_a . Such an exponential screening, strictly spoken, occurs only for London superconductors with large GL-parameter $\kappa \gg 1$, while for smaller κ values both $|\psi|$ and B vary near the surface and have to be obtained by solving the GL equations. Moreover, for superconductors of realistic shape, such as short cylinders or rectangular plates, the penetration of a magnetic field into the surface layer has to be calculated numerically; only for spheres and long cylinders with $\kappa \gg 1$, analytical solutions were obtained by London.

Critical fields

In type-I superconductors (defined by $\kappa < 1/\sqrt{2}$), complete screening occurs when the applied magnetic field H_a is less than the thermodynamic critical field $H_c = \mu_0^{-1}B_c$; in larger fields $H_a \geq H_c$, these superconductors are normal conducting. For type-II superconductors (defined by $\kappa \geq 1/\sqrt{2}$), full screening occurs up to the lower critical field $H_{c1} = \mu_0^{-1}B_{c1}$ where penetration of Abrikosov vortices begins. With a further increasing of H_a , more vortices penetrate in the form of a more or less regular flux-line

Fig. 1 The triangular vortex lattice. The dots mark the positions of vortex cores. From Brandt E.H. (2005) Superconductivity: Ginzburg-Landau theory and vortex lattice. *Encyclopedia of Condense Matter Physics*, 1st edn., pp. 98–105. Elsevier.

lattice (Fig. 1), which has an average induction $\bar{B} = n\Phi_0$, where n is the area-density of vortices and $\Phi_0 = 2.07 \times 10^{-15} \text{ Tm}^2$ is the quantum of magnetic flux. When H_a reaches the upper critical field $H_{c2} = \mu_0^{-1}B_{c2}$, the vortex cores overlap so strongly that the superconductor turns normal and one has $\bar{B} = \mu_0 H_a > B_{c2}$. The GL theory yields

$$B_{c1} = \frac{\Phi_0 (\ln \kappa + \alpha)}{4\pi\lambda^2}, \quad B_c = \frac{\Phi_0}{\sqrt{8\pi}\lambda\xi}, \quad B_{c2} = \frac{\Phi_0}{2\pi\xi^2} \quad (2)$$

with $\alpha(\kappa) \approx 0.5 + (1 + \ln 2)/(2\kappa - \sqrt{2} + 2)$ (Brandt, 2003). At $\kappa = 1/\sqrt{2}$, one has exactly $B_{c1} = B_c = B_{c2}$, and for type-II superconductors $B_{c1} \leq B_c \leq B_{c2}$. In both types of superconductors, B_c determines the area under the magnetization curve $\mu_0 M(H_a)$; this area equals the superconducting condensation energy B_c^2/μ_0 . For ideal pin-free superconductors, the magnetization is $M = \mu_0^{-1}\bar{B} - H_a \leq 0$, see Fig. 2. For type-II superconductors with an ideal planar surface, H_c is also the field up to which the so-called Bean-Livingston surface barrier may prevent a vortex penetration ("overheating"). Interestingly, as discovered theoretically by De Gennes in 1963, even above B_{c2} , a thin surface sheath of thickness ξ remains superconducting up to a third critical field, $B_{c3} = 1.695B_{c2}$ (De Gennes, 1966).

The above scenario applies to long superconductors in the parallel magnetic field H_a . In realistic samples like spheres, platelets, or films, demagnetization effects lead to flux penetration at lower fields. In ideal ellipsoids, the penetration fields, H_c or H_{c1} , are reduced by a factor $1-N$, where N is the demagnetization factor. For spheres, one has $N = 1/3$, and for long cylinders, $N = 0$ in a parallel field and $N = 1/2$ in a perpendicular field, while for thin plates in a perpendicular field, one has $1 - N \ll 1$, and thus very small fields will force flux penetration from the edges.

In type-I superconductors with $N > 0$, demagnetization effects lead to partial penetration of flux in the form of planar domains or more complicated structures, while in type-II superconductors they just shear the magnetization curve, but the vortex lattice remains uniform if the specimen is an ellipsoid. For other shapes such as platelets, strips, or disks with constant thickness, the demagnetization effects are more complicated and lead to a geometrical barrier for flux penetration, with a penetration field which is approximately H_{c1} times the square root of the aspect ratio thickness/width (Brandt et al., 2013; Zeldov et al., 1994). For specimens much larger than λ , this result can be derived by the continuum theory without considering individual vortex lines. But for small mesoscopic superconductors with size comparable to or smaller than λ , the full GL theory has to be solved numerically to see the detailed pattern of penetrated flux lines and the shape of the magnetization curve $M(H_a)$ that may exhibit jumps at certain values of H_a .

Vortex lattice

Abrikosov (1957) found a solution of the GL theory that exhibits a two-dimensional (2D) regular lattice of zeros in the order parameter $\psi(x, y)$ and a periodic magnetic field $B(x, y)$. This solution describes a lattice of parallel vortex lines along z . The ideal lattice is triangular, that is, each vortex has six nearest neighbors, see Fig. 1. The vortices start penetrating at $H_a = H_{c1}$. The profiles $|\psi(r)|^2$ and $B(r)$ of one isolated vortex line are shown in Fig. 3 (r is the radial coordinate). As H_a is increased, more vortices penetrate and form a vortex lattice as shown in Fig. 4. First, the magnetic fields of the flux lines overlap, such that the amplitude of the periodic $B(x, y)$ decreases. Then, the cores also overlap, such that the amplitude of the order parameter $|\psi|^2$ decreases until it vanishes at $H_a = H_{c2}$. For $b = \bar{B}/B_{c2} > 0.5$, good approximations are (Brandt, 1995)

$$|\Psi(\mathbf{r})|^2 = \frac{1 - \bar{B}/B_{c2}}{[1 - 1/(2\kappa^2)]\beta_A + 1} \sum_{\mathbf{K}} a_{\mathbf{K}} \cos \mathbf{K}\mathbf{r}, \quad (3)$$

Fig. 2 Magnetization curves $M(H)$ of long type-II superconductors in parallel magnetic field $H = H_a$ (demagnetization factor $N = 0$) calculated from Ginzburg-Landau theory for various Ginzburg-Landau parameters $\kappa = 0.75 \dots 3$. For $\kappa = 1/\sqrt{2}$, $-M$ jumps vertically from $-M = H$ to $M = 0$ at $H = H_{c1} = H_{c2}$.

Fig. 3 Magnetic field $B(r)$ and order parameter $|\psi(r)|^2$ of an isolated flux line calculated from the Ginzburg-Landau theory for Ginzburg-Landau parameters $\kappa = 2, 5$, and 20 .

Fig. 4 Two profiles of the magnetic field $B(x, y)$ and order parameter $|\Psi(x, y)|^2$ along the x -axis (a nearest-neighbor direction) for flux-line lattices with lattice spacing $a = 4\lambda$ (bold lines) and $a = 2\lambda$ (thin lines). The dashed line shows the magnetic field of an isolated flux line from Fig. 3. Calculations from the Ginzburg-Landau theory for $\kappa = 5$.

$$B(\mathbf{r}) = \mu_0 H_a - \frac{\Phi_0}{4\pi\lambda^2} |\Psi(\mathbf{r})|^2. \quad (4)$$

Here $\mathbf{r} = (x, y)$ and the sum is over all reciprocal lattice vectors $K_{mn} = (2\pi/x_1 y_2)(m y_2; -m x_2 + n x_1)$ of the periodic flux-line lattice (FLL) with fluxline positions $R_{mn} = (m x_1 + n x_2; m y_2)$ (m, n = integer). The unit-cell area $x_1 y_2$ yields the mean induction $\bar{B} = \Phi_0/x_1 y_2$. The first Brillouin zone has the area πk_{BZ}^2 with $k_{BZ}^2 = 4\pi\bar{B}/\Phi_0$. For general lattice symmetry, the Fourier coefficients a_K and the Abrikosov parameter β_A are:

$$a_K = (-1)^{m+mn+n} \exp(-K_{mn}^2 x_1 y_2 / 8\pi), \quad (5)$$

$$\beta_A = \frac{\langle |\Psi|^4 \rangle}{\langle |\Psi|^2 \rangle^2} = \sum_K a_K^2. \quad (6)$$

From $\psi(\mathbf{r} = 0) = 0$ follows $\sum_K a_K = 0$, or with $a_{K=0} = 1$, $\sum_{K \neq 0} a_K = -1$. In particular, for the triangular vortex lattice with spacing $a = (2\Phi_0/\sqrt{3}\bar{B})^{1/2}$, one has $x_1 = a, x_2 = a/2, y_2 = \sqrt{3}a/2, \bar{B} = 2\Phi_0/(\sqrt{3}a^2), a_K = (-1)^p \exp(-\pi p/\sqrt{3})$ with $p = m^2 + mn + n^2 = R_{mn}^2/R_{10}^2$. This yields $\beta_A = 1.15960$ (the reciprocal-lattice sum converges very rapidly) and the useful relationships

$K_{10} = 2\pi/\gamma_2, K_{10}^2 = 16\pi^2/3a^2 = 8\pi^2\bar{B}/\sqrt{3}\Phi_0$. For square vortex lattice, one has $x_1 = y_2 = a, x_2 = 0, \bar{B} = \Phi_0/a^2$, and $\beta_A = 1.18034$. This means the energy of the square vortex lattice is only slightly larger than that of the triangular lattice, by 2% at most. A vortex lattice with square symmetry has been observed experimentally, for example, when the underlying square symmetry of the atomic lattice couples to the vortex lattice such that the square vortex lattice has lower energy, but also other effects may stabilize the square lattice, for example, an anisotropic Fermi surface or a deviation from the GL theory.

The free energy $F(\bar{B})$ per unit volume and the negative magnetization $-M = H_a - \mu_0^{-1}\bar{B} \geq 0$ with $H_a = \partial F/\partial \bar{B}$ are (still for $\bar{B}/B_{c2} > 0.5$ and from the GL theory):

$$F(\bar{B}) = \frac{\bar{B}^2}{2\mu_0} - \frac{(B_{c2} - \bar{B})^2}{(2\kappa^2 - 1)\beta_A + 1}, \quad (7)$$

$$-\mu_0 M(\bar{B}) = \frac{(B_{c2} - \bar{B})}{(2\kappa^2 - 1)\beta_A + 1} = \frac{\Phi_0}{4\pi\lambda^2} < |\Psi|^2 >. \quad (8)$$

For the periodic field $B(\mathbf{r}) = \sum_{\mathbf{K}} B_{\mathbf{K}} \cos \mathbf{K}\mathbf{r}$, the Fourier coefficients are $B_{\mathbf{K} \neq 0} = \mu_0 M a_{\mathbf{K}}, B_{\mathbf{K}=0} = \bar{B}$, and $< |\Psi|^2 > = (4\pi\lambda^2/\Phi_0)\mu_0 |M|$.

At lower induction $\bar{B}/B_{c2} < 0.5$, the vortex lattice and its magnetization curve have to be computed from the GL theory numerically, see Figs. 2–4. However, when $\kappa \gg 1$, one may also use the London theory, which is a good approximation for small inductions $\bar{B}/B_{c2} < 0.2$.

London theory

The London theory follows from the GL theory by putting $|\psi| = 1$, but it may also be obtained by minimizing the sum F of the energy of the magnetic field $B(\mathbf{r})$ and the kinetic energy of the supercurrent density $\mathbf{J}(\mathbf{r}) = \mu_0^{-1} \nabla \times \mathbf{B}(\mathbf{r})$. This yields the London energy functional

$$F(B) = \frac{1}{2\mu_0} \int_V [B^2 + \lambda^2 (\nabla \times \mathbf{B})^2] d^3r. \quad (9)$$

Minimizing this with respect to $\mathbf{B} = \nabla \times \mathbf{A}$, one obtains the homogeneous London equation $\mathbf{B} - \lambda^2 \nabla^2 \mathbf{B} = 0$ or $\mathbf{J} = -\mu_0^{-1} \lambda^{-2} \mathbf{A}$ where the Maxwell equations $\nabla \cdot \mathbf{B} = 0$ and $\nabla \times \mathbf{B} = \mu_0 \mathbf{J}$ were used, and the vector potential $\mathbf{A}$ was chosen in the “London gauge,” which requires that $\nabla \cdot \mathbf{A} = 0$ and $\mathbf{A}$ is parallel to the surface everywhere. In presence of vortices, one has to add singularities that describe the vortex core, which may be straight or curved.

For straight parallel vortex lines along the unit vector $\mathbf{z}$, one gets the modified London equation

$$\mathbf{B} - \lambda^2 \nabla^2 \mathbf{B} = \mathbf{z} \Phi_0 \sum_v \delta_2(\mathbf{r} - \mathbf{r}_v). \quad (10)$$

Here $\mathbf{r}_v = (x_v, y_v)$ are the 2D vortex positions, which now do not have to form a periodic lattice, and $\delta_2(\mathbf{r}) = \delta(x)\delta(y)$ is the 2D delta function. This linear equation may be solved by Fourier transform using the relations $\int \exp(i\mathbf{k}\mathbf{r}) d^2k = 4\pi^2 \delta_2(\mathbf{r})$ and $\int \exp(i\mathbf{k}\mathbf{r}) (k^2 + \lambda^{-2})^{-1} d^2k = 2\pi K_0(|\mathbf{r}|/\lambda)$. Here, $K_0(x)$ is a modified Bessel function with the limits $K_0(x) \approx \ln(1.123/x)$ for $x \ll 1$ and $K_0(x) \approx (\pi/2x)^{1/2} \exp(-x)$ for $x \gg 1$. The resulting magnetic field of any arrangement of parallel vortices is the sum of individual London vortex fields centered at the positions $\mathbf{r}_v$,

$$\mathbf{B}(\mathbf{r}) = \mathbf{z} \frac{\Phi_0}{2\pi\lambda^2} \sum_v K_0\left(\frac{|\mathbf{r} - \mathbf{r}_v|}{\lambda}\right). \quad (11)$$

The energy F_{2D} of this 2D arrangement of vortex lines with length L (the specimen height) is obtained by inserting Eq. (10) into Eq. (9). Integrating over the delta function, one finds that the London energy is determined by the magnetic field values at the vortex positions,

$$F_{2D} = L \frac{\Phi_0}{2\mu_0} \sum_{\mu} B(\mathbf{r}_{\mu}) = L \frac{\Phi_0^2}{4\pi\mu_0\lambda^2} \sum_{\mu} \sum_v K_0\left(\frac{|\mathbf{r}_{\mu} - \mathbf{r}_v|}{\lambda}\right). \quad (12)$$

This expression shows that the energy is composed of the pairwise interaction energy (terms $\mu \neq v$) and the self-energy of the vortices (terms $\mu = v$). To avoid the divergence of the self-energy, one has to cut off the logarithmic infinity of B at the vortex centers $\mathbf{r}_v$ by introducing a finite radius of the vortex core of order ξ , the coherence length of the GL theory. This cutoff may be achieved by replacing, in Eqs. (11) and (12), the distance $r_{\mu v} = |\mathbf{r}_{\mu} - \mathbf{r}_v|$ by $\tilde{r}_{\mu v} = (r_{\mu v}^2 + 2\xi^2)^{1/2}$, and multiplying B by a normalization factor ≈ 1 to conserve the flux Φ_0 of the vortex. This analytical expression suggested by John Clem for a single vortex and later generalized to the vortex lattice (Hao et al., 1991), is an excellent approximation, as was shown numerically by solving the GL equation for the periodic FLL in the entire ranges of $\bar{B}$ and κ for $0 \leq \bar{B} \leq B_{c2}$ and $\kappa \geq 1/\sqrt{2}$ (Brandt, 1997).

For curved vortices at arbitrary positions $\mathbf{r}_v(z) = [x_v(z), y_v(z), z]$, the 3D modified London equation reads

$$\mathbf{B} - \lambda^2 \nabla^2 \mathbf{B} = \Phi_0 \sum_v \int d\mathbf{r}_v \delta_3(\mathbf{r} - \mathbf{r}_v). \quad (13)$$

Here, the integral is along the vortex lines and $\delta_3(\mathbf{r}) = \delta(x)\delta(y)\delta(z)$. The resulting magnetic field and energy are, with $\tilde{r}_{\mu\nu} = \left[|\mathbf{r}_\mu - \mathbf{r}_\nu|^2 + 2\zeta^2 \right]^{1/2}$,

$$\mathbf{B}(\mathbf{r}) = \frac{\Phi_0}{4\pi\lambda^2} \sum_v \int d\mathbf{r}_v \frac{\exp[-\tilde{r}_{\mu\nu}(\mathbf{r}_\mu = \mathbf{r})/\lambda]}{\tilde{r}_{\mu\nu}(\mathbf{r}_\mu = \mathbf{r})}, \quad (14)$$

$$F_{3D} = \frac{\Phi_0}{2\mu_0} \sum_\mu \int d\mathbf{r}_\mu B(\mathbf{r}_\mu) = \frac{\Phi_0^2}{8\pi\mu_0\lambda^2} \sum_\mu \sum_\nu \int d\mathbf{r}_\mu \int d\mathbf{r}_\nu \frac{\exp(-\tilde{r}_{\mu\nu}/\lambda)}{\tilde{r}_{\mu\nu}}.$$

This means all the vortex segments interact with each other similar to magnetic dipoles or tiny current loops, but the magnetic long-range interaction $\propto 1/r$ is screened by a factor $\exp(-\tilde{r}_{\mu\nu}/\lambda)$. The 3D interaction between curved vortices is visualized in Fig. 5.

Vortices near surfaces and in films

The above London solutions apply to vortices in the bulk. Near the surface of the superconductor, these expressions have to be modified. In simple geometries, for example, for superconductors with one or two planar surfaces surrounded by vacuum, the magnetic field and energy of a given vortex arrangement is obtained by adding the field of appropriate images (in order to satisfy the boundary condition that no current crosses the surface) and a magnetic stray field which is caused by a fictitious surface layer of magnetic monopoles. This stray field makes the total magnetic field $B(\mathbf{r})$ continuous across the surface. Fig. 6 shows an example for this.

The magnetic field and interaction of straight vortices oriented perpendicular to a superconducting film of arbitrary thickness was calculated by Carneiro and Brandt (2000) from the London theory and by Brandt (2005) from the GL theory. In films of thickness $d \ll \lambda$ in a perpendicular magnetic field, the short vortices interact mainly via their magnetic stray field outside the superconductor over an effective penetration depth $\Lambda = 2\lambda^2/d$. With decreasing thickness d , the Fourier transform of the 2D vortex interaction $V(r) = \int (d^2k/4\pi^2) \tilde{V}(k) \exp(i\mathbf{k}\mathbf{r})$ changes from $\tilde{V}(k) = E_0(k^2 + \lambda^{-2})^{-1}$ for $d \gg \lambda$ to $\tilde{V}(k) = E_0(k^2 + k\Lambda^{-1})^{-1}$ for $d \ll \lambda$, where $E_0 = d\Phi_0^2/(\mu_0\lambda^2)$.

Interaction between curved flux lines

Fig. 5 Pairwise interaction between all line elements (arrows) of curved flux lines within the London theory (schematic).

Fig. 6 Magnetic field lines of a straight vortex in and near a superconducting half space. From the London theory, for $\kappa = 20$. The dashed lines give the radial field lines of a magnetic charge of size $2\Phi_0$ positioned on the vortex axis at a depth $-z_0 = \lambda$ (left half, the far field) and $-z_0 = 1.27\lambda$ (right half), which gives a better fit to the near field. The lower plot enlarges the center of the upper plot.

As shown by Clem (1991), a similar (but 3D) magnetic interaction exists between the 2D “pancake vortices” in the superconducting Cu-O layers of high- T_c superconductors, $\tilde{V}(k) = E_0 d k_3^2 k_2^{-2} (\lambda^{-2} + k_3^2)^{-1}$, where now d is the distance between the layers, $k_2^2 = k_x^2 + k_y^2$, $k_3^2 = k_z^2$, and $\lambda = \lambda_{ab}$ is the penetration depth for the supercurrents flowing in these layers.

Elasticity of the vortex lattice

Small flux-line displacements caused by pinning forces or by thermal fluctuations may be calculated using the linear elasticity theory of the vortex lattice. Fig. 7 visualizes the three basic distortions of the triangular vortex lattice: shear γ , uniaxial compression ε , and tilt α , defining the three elastic moduli c_{66} , c_{11} , and c_{44} and the naive (local) elastic energy

$$F_{\text{elast}} = \frac{V}{2} [c_{11}\varepsilon^2 + c_{66}\gamma^2 + c_{44}\alpha^2]. \quad (15)$$

The linear elastic energy F_{elast} of the vortex lattice is obtained by expanding its free energy F with respect to small displacements $\mathbf{u}_v(z) = \mathbf{r}_v(z) - \mathbf{R}_v = (u_{vx}, u_{vy})$ of the vortices from their ideal parallel lattice positions $\mathbf{R}_v$ and keeping only the quadratic terms. This yields (Brandt, 1995)

Fig. 7 The three basic homogeneous elastic distortions of the triangular vortex lattice. The full dots and solid lines mark the ideal lattice, and the hollow dots and dashed lines the distorted lattice.

$$F_{\text{elast}} = \frac{1}{2} \int_{\text{BZ}} \frac{d^3 k}{8\pi^3} u_{\alpha}(\mathbf{k}) \Phi_{\alpha\beta}(\mathbf{k}) u_{\beta}^*(\mathbf{k}), \quad (16)$$

where $u(\mathbf{k})$ is the Fourier transform of the displacement field $u_{\nu}(z)$, $(\alpha, \beta) = (x, y)$, and $\mathbf{k} = (k_x, k_y, k_z)$. The k -integral in Eq. (16) is over the Brillouin zone (BZ) of the FLL since the “elastic matrix” $\Phi_{\alpha\beta}(\mathbf{k})$ is periodic in the k_x, k_y plane; the finite vortex core radius restricts the k_z integration to $|k_z| \leq \xi^{-1}$. For an elastic medium with uniaxial symmetry, the elastic matrix reads

$$\Phi_{\alpha\beta}(\mathbf{k}) = (c_{11} - c_{66})k_{\alpha}k_{\beta} + \delta_{\alpha\beta} \left[(k_x^2 + k_y^2)c_{66} + k_z^2 c_{44} \right]. \quad (17)$$

Here the coefficients c_{11} , c_{66} , and c_{44} are the elastic moduli of uniaxial compression, shear, and tilt, respectively. For the vortex lattice, $\Phi_{\alpha\beta}(\mathbf{k})$ was calculated from the GL and London theories. The result, a sum over reciprocal lattice vectors, should coincide with expression (17) in the continuum limit, that is, for small $|\mathbf{k}| \ll k_{\text{BZ}}$, where $k_{\text{BZ}} = (4\pi\bar{B}/\Phi_0)^{1/2}$ is the radius of the circularized (actually hexagonal) Brillouin zone of the triangle vortex lattice with area πk_{BZ}^2 . In the London limit, one finds for isotropic superconductors, the elastic moduli (Blatter et al., 1994; Brandt, 1995)

$$\begin{aligned} c_{11}(k) &\approx \frac{\bar{B}^2/\mu_0}{1 + k^2\lambda^2}, \quad c_{66} \approx \frac{\bar{B}\Phi_0/\mu_0}{16\pi\lambda^2}, \\ c_{44}(\mathbf{k}) &\approx \frac{\bar{B}^2/\mu_0}{1 + k^2\lambda^2} + \frac{\bar{B}\Phi_0/\mu_0}{8\pi\lambda^2} \ln \frac{\kappa^2}{1 + k_z^2\lambda^2}. \end{aligned} \quad (18)$$

The GL theory yields an additional factor $(1 - \bar{B}/B_{c2})^2$ in c_{66} , that is, $c_{66} \propto \bar{B}(\bar{B} - B_{c2})^2$, and replaces λ in c_{11} and c_{44} (first term) by $\lambda' = \lambda/(1 - \bar{B}/B_{c2})^{1/2}$ (Brandt, 1995).

The k dependence (dispersion) of the compression and tilt moduli $c_{11}(k)$ and $c_{44}(\mathbf{k})$ means that the elasticity of the vortex lattice is nonlocal, that is, strains with short wavelengths, $2\pi/k \ll 2\pi\lambda$, have a much lower elastic energy than a homogeneous compression or tilt (corresponding to $k \rightarrow 0$) with the same amplitude. This elastic nonlocality comes from the fact that the magnetic interaction between the flux lines typically has a range λ much longer than the flux-line spacing a_0 ; therefore, each flux line interacts with many other flux lines. Note that a large λ causes a small shear stiffness since $c_{66} \propto \lambda^{-2}$, and a smaller $c_{11}(k > \lambda^{-1})$ at short wavelengths, but the uniform compressibility $c_{11}(k = 0)$ is independent of λ .

As a consequence of nonlocal elasticity, vortex displacement $\mathbf{u}_{\nu}(z)$ caused by local pinning forces, and also the space- and time-averaged thermal fluctuations of the vortex positions, $\langle u_{\nu}(z)^2 \rangle$, are much larger than they would be if $c_{44}(\mathbf{k})$ had no

dispersion, that is, if it were replaced by $c_{44}(0) = \bar{B}H_a \approx \bar{B}^2/\mu_0$. The maximum vortex displacement $u(0) \propto f$ caused at $r = 0$ by a point force of density $f\delta_3(\mathbf{r})$, and the thermal fluctuations $\langle u^2 \rangle \propto k_B T$, are given by similar expressions (Brandt, 1995),

$$\frac{2u(0)}{f} \approx \frac{\langle u^2 \rangle}{k_B T} \approx \int_{\text{BZ}} \frac{d^3 k}{8\pi^3} \frac{1}{(k_x^2 + k_y^2)c_{66} + k_z^2 c_{44}(\mathbf{k})} \approx \frac{k_{\text{BZ}}^2 \lambda}{8\pi [c_{66}c_{44}(0)]^{1/2}}. \quad (19)$$

In this result, a large factor $[c_{44}(0)/c_{44}(k_{\text{BZ}})]^{1/2} \approx k_{\text{BZ}}\lambda \approx \pi\lambda/a \gg 1$ originates from the elastic nonlocality. In anisotropic superconductors with $B \parallel c$ (the crystalline c axis), the thermal fluctuations, Eq. (19), are enhanced by an additional factor $\Gamma = \lambda_c/\lambda_{ab} \gg 1$, where λ_{ab} and λ_c are the two penetration depths of uniaxially anisotropic superconductors.

Conclusion

The phenomenological London and Ginzburg-Landau theories are effective tools for investigating both low- T_c and high- T_c superconductors. These theories permit one to understand the thermodynamic properties of superconducting materials and to describe the vortex lattice in type-II superconductors even without any information on the microscopic mechanism of the superconductivity. In particular, the lattices of straight and curved vortices, the vortices in films, and the vortex-lattice elasticity, which is a necessary constituent of an analysis of the vortex pinning, have been considered in the framework of this approach.

Abstract

The fabrication methods, principle of operation, microstructural, and electron transport properties, as well as the application of nanoscale superconducting quantum interference devices (nanoSQUIDs) are considered. NanoSQUIDs by definition have a submicrometer loop size, which limits dimensions of Josephson junctions to about 100 nm or less. This makes the use of tunnel junctions problematic, but encourages the use of nanobridges and other types of Josephson junctions with high critical current densities. The use of nitride superconductors helps to optimize the superconducting parameters and enhances the corrosion resistance of the nanobridge Josephson junctions and nanoSQUIDs. Additional passivation by a Si layer improves thermal sink and protects against the mechanical and electrical fragility of the devices. Nanosculpturing of cantilevers makes it possible to position the nanoSQUID at a distance of 10–100 nm from the objects under study in the nanoSQUID scanning measurement system. Several promising applications of nanoSQUIDs are briefly reviewed.

Key points

- NanoSQUIDs with a sub-micrometer loop size and dimensions of Josephson junctions to about 100 nm or less.
- The use of nanobridges and other types of Josephson junctions with high critical current densities.
- The use of nitride superconductors to optimize the superconducting parameters and to enhance the corrosion resistance of the Josephson junctions and nanoSQUIDs.
- Passivation by a Si layer to improve thermal sink and protect against the mechanical and electrical fragility of the devices.
- Nanosculpturing of cantilevers makes it possible to position the nanoSQUID at a distance of 10–100 nm from the objects under study in the nanoSQUID scanning system.
- Several promising applications of nanoSQUIDs are considered.

Introduction

A nanoscale Superconducting QUantum Interference Device (nanoSQUID) is defined as a submicron loop of superconducting material that is interrupted by at least one Josephson junction. Josephson junctions are weak links connecting two superconducting leads. These weak links can be made by many different methods: using tunnel barriers, normal conducting or semiconducting interlayers, by superconducting interlayer with lower T_c as in the electrodes, or using short narrow constrictions (nanobridges).

NanoSQUIDs are among the most sensitive tools for measuring very weak magnetic fields with high spatial resolution down to a few nanometers (Anahory et al., 2020; Granata and Vettoliere, 2016; Foley and Hilgenkamp, 2009). The submicron size of the nanoSQUID loop imposes serious limitations on the size of Josephson junctions: Typical Josephson junction sizes for implementation in nanoSQUIDs are around 300 nm, or more often below 100 nm when better spatial resolution is required. This makes the use of tunnel junctions problematic, but encourages the use of single layer short narrow constrictions (nanobridges) and other types of Josephson junctions with high critical current densities. Tunnel types of Josephson junction are traditionally used in superconducting electronics and currently also in superconducting quantum bits (qubits). The resistively shunted tunnel Josephson junctions, which have been designed for most applications in superconducting electronics, are typically a few micrometers in size (together with the shunt resistor) and do not fit inside nanoSQUIDs. In the case of submicron junctions, the realization of the three-layer structure with internally shunted junctions in the form of thinner tunnel junctions that are used for qubits or with a normal or a semiconductor conductor barrier is technologically relatively complex and associated with an increasing scattering of the junction parameters. An exceptional example is a nanosculpturing of tunnel junctions using a focused ion beam (FIB) that makes it possible to achieve high critical current modulation depth, non-hysteretic $I(V)$ -characteristics at 4.2 K and a record energy resolution of about $1.3 h$, where h is Planck's constant (Schmelz et al., 2017). The renaissance of nanobridge Josephson junctions (nJJs) is observed in the case of nanoSQUIDs after more than 40 years of dominance of tunneling Josephson junctions for other applications in superconducting electronics. The great advantage of nJJs especially for preparation of planar nanoSQUIDs is

that their size is limited only by the spatial resolution of the single layer patterning methods, and the possibility to achieve the highest critical current density that approaches the depairing current densities in the superconducting films.

The operating temperature of nanoSQUIDs is lower than the superconducting transition temperature T_c of the superconducting material, and it is typically liquid helium temperature 4.2 K or lower for low-temperature superconductors such as Nb, NbN, TiN, etc., or liquid nitrogen temperature 77.4 K or lower for high-temperature superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$. The use of nitride superconductors helps to optimize the superconducting parameters and enhances the corrosion resistance of the Josephson junctions and nanoSQUIDs. Additional passivation by a Si layer can improve thermal sink and protect against the mechanical and electrical fragility of the devices. Nanosculpturing of cantilevers makes it possible to position the nanoSQUID at a distance of 10–100 nm from the objects under study in the nanoSQUID scanning system. Attocube's low temperature positioning and scanning system allows extremely large scanning of areas up to 5×5 mm with sub-nm spatial resolution at 4.2 K.

NanoSQUIDs are designed to study small magnetic systems like magnetic nanoparticles or current distribution at low temperatures with nanoscale spatial resolution down to ~ 40 nm and high sensitivity to tiny magnetic moments that is expressed in the units of spin sensitivity $\mu_B/\sqrt{\text{Hz}}$, where $\mu_B \cong 9.27 \times 10^{-24}$ J/T is Bohr magneton. Currently, the best nanoSQUIDs are able to measure distribution of magnetic fields of single atomic spins with spin sensitivity $< 1 \mu_B/\sqrt{\text{Hz}}$ (Vasyukov et al., 2013; Anahory et al., 2020). NanoSQUID microscopy competes with diamond microscopy, which is based on negatively charged nitrogen vacancy (NV) centers in diamond, and demonstrated nanoscale magnetic imaging of a single electron spin when operated at room temperature. Low operation temperatures of nanoSQUIDs can be useful in studying properties of small magnetic systems at low temperatures, transition edge detectors for single photon, macromolecule detection and for applications in superconducting quantum technologies, such as quantum metrology and low dissipation readout of quantum bits (qubits).

Overview

NanoSQUID is a nanoscale subtype of a superconducting quantum interference device (SQUID) that represents a superconducting loop interrupted by at least one Josephson junction. SQUID uses the amplitude and phase of wave function of Cooper pairs to detect small magnetic fluxes threading the SQUID loop. Contrary to uninterrupted superconducting loop, magnetic flux through the SQUID loop can take arbitrary values because a part of phase difference can be accommodated on the Josephson junctions and be measured using Josephson's current-phase relation that is periodic with a magnetic flux quantum $\Phi_0 = h/2e \cong 2.068 \text{ fT m}^2$. In the case of only one Josephson contact, no leads are attached to the SQUID and the coupling to the readout electronics takes place inductively at a radio frequency. Such single Josephson junction SQUID is called an RF SQUID. In some cases also SQUIDs containing several Josephson junctions are inductively coupled to RF readout electronics and operate as RF SQUIDs (Zhang et al., 1993). As the size of the SQUID circuit is reduced, the inductive coupling becomes weaker, but this can be partially compensated by galvanic coupling and a corresponding resonant circuit. The smallest pickup loops of RF SQUIDs implemented for SQUID microscopy have a diameter of $\sim 1 \mu\text{m}$ (Foroughi et al., 2018). Direct current SQUID (DC SQUID) has a parallel connection of at least two Josephson junctions between two superconducting electrodes on a closed superconducting loop. It can be biased by a current above the critical current of the transitions to their voltage state, which is easier compared to controlling the operation of RF SQUIDs, especially at submicron SQUID sizes. This explains the exclusive use of the DC SQUID in the design of nanoSQUIDs, and only these will be described later in this review.

The superconducting loop of the DC-SQUID contains two or more Josephson junctions and galvanic connections to the readout electronics that allow the DC-SQUID to be biased to a voltage state. DC SQUIDs act as magnetic flux to voltage converters because they convert the magnetic flux penetrating the DC SQUID loop to voltage on the DC SQUID. Operation of DC SQUIDs is based on the dependence of the canonical momentum of charged particles on the vector potential of magnetic field $\vec{p} = m\vec{v} + q\vec{A}$, where the charge $q = -2e$ for the case of Cooper pairs in superconducting electrodes of a DC SQUID: see Fig. 1. Consequently, de Broglie wavelength of the Cooper pairs $\lambda = h/|\vec{p}|$ and their wave vector $\vec{k} = 2\pi\vec{p}/h$ are dependent on the local values of the vector potential. As a result, phase shift $\delta\varphi = \int \vec{k} d\vec{l}$ of Cooper pair's wave function acquired when moving Cooper pairs around the hole in the SQUID loop is determined by the magnetic flux Φ penetrating through the loop. The Cooper pairs travel inside superconductors that in ideal case shields completely from magnetic field. Nevertheless, the vector potential of magnetic field is present inside superconductor and it changes the de Broglie wavelength and the wave vector of the Cooper pairs. The total phase shift acquired by the Cooper pair when moving along the SQUID loop is determined only by the magnetic flux through the loop and does not

Fig. 1 Schematic representation of a DC SQUID loop with values of the impulse p of Cooper pairs and magnetic flux Φ through the loop.

depend on the shape of the loop. This is a type of Berry phase, similar to the phase that a single electron receives in the Aharonov-Bohm effect used in modified for electron holography measurements transmission electron microscopes (Dunin-Borkowski, 1998).

Maximal superconducting current $I_s(\max)$ of DC SQUID is a periodical function of the magnetic flux Φ penetrating through the loop:

$$I_s = 2I_C \left| \cos \frac{\pi\Phi}{\Phi_0} \right|, \quad (1)$$

where $\Phi_0 = h/2e \cong 2.068 \text{ fT m}^2$ is a magnetic flux quantum.

Josephson junctions convert the phase shift into voltage when the DC-SQUID is biased with a bias current I_B slightly higher than the sum of the critical currents $2I_C$ of the Josephson junctions in the absence of magnetic field. Above I_C voltage $U(t)$ across a Josephson junction oscillates in the form of periodic pulses (Josephson oscillations). At bias currents $I_B > 2I_C$ similar voltage pulses $U(\Phi, t)$ proceed on DC SQUID but they depend also on magnetic flux Φ passing through the SQUID loop due to the phase difference between the Josephson oscillations on individual junctions. Averaging of $U(\Phi, t)$ over the period τ of the Josephson oscillations results in the DC voltage V across the DC SQUID:

$$V = \frac{1}{\tau} \int_0^\tau U(\Phi, t) dt \approx \frac{R_N I_B}{2} \sqrt{1 - \left(\frac{2I_C}{I_B} \cos \frac{\pi\Phi}{\Phi_0} \right)^2}, \quad (2)$$

where R_N is the normal state resistance of the individual Josephson junction in the DC SQUID. The DC voltage V across the DC SQUID is thus a periodic function of the magnetic flux Φ passing through the SQUID loop.

Eq. (2) was obtained under the assumption of a negligible inductance of nanoSQUIDs. The non-zero inductance L_s reduces modulation of critical current of DC SQUID to $\Delta I_s(\max) \sim \Phi_0/L_s$. By increasing L_s , the optimal modulation parameter $\beta_L = 2L_s I_C / \Phi_0 \cong 1$ for DC SQUIDs corresponds to still large modulation of critical current and already good magnetic coupling to the measured signal. Responsible for magnetic coupling, geometrical inductance of nanoSQUID is typically below 0.5 pH and typical critical current is limited to $I_C \sim 20 \text{ }\mu\text{A}$ even for nJJs in order to avoid hysteretic $I(V)$ -characteristics. Taking into account only the geometrical inductance corresponds to the modulation parameter $\beta_L \cong 0.01$. On the other hand, kinetic inductance of the nanoSQUID loop $L_{ks} \cong 2\pi\mu_0\lambda_L^2 R/A \cong 60 \text{ pH}$, where (for example) $R \cong 300 \text{ nm}$ is the nanoSQUID's loop radius, $\lambda_L \cong 500 \text{ nm}$ is London penetration depth in superconducting film of the loop and $A \cong 0.01 \text{ }\mu\text{m}^2$ is the estimated cross sectional area of the loop. This corresponds to the boundary value of the modulation parameter $\beta_L \cong 1.1$. The task of optimizing nanoSQUIDs includes taking into account its kinetic inductance, limiting it, and finding ways to reduce it through the correct design, technology, and choice of material. The theoretical expectation for kinetic inductance of a nanobridge $L_{kn} \cong \gamma \frac{1}{w} \frac{\hbar R}{k_B T_c}$, where ℓ and w are length and width of nanobridge, $\gamma \cong 0.2$ and $R_\bullet$ is the normal-state sheet resistance of the superconducting film.

The Josephson current-phase relation $I_s = I_c \sin(\Delta\varphi)$ is realized in Josephson junctions made by different methods in spite of variety of used electron-transport mechanisms: tunneling effect in insulator barrier, proximity effect in normal conducting and semiconducting barriers or spatially constricted superconducting current in nJJs. Operation principle of tunnel and proximity effect Josephson junctions is well described in many current textbooks and handbooks (see, for example, (Mangin and Kahn, 2017) and (Ruggiero, 2015)) as a standard explanation of Josephson effect because such 3-layer junctions are the most widely used type of Josephson junction in conventional superconducting electronics. Tunnel junctions are currently also effectively used in qubits (e.g., flux qubits and transmons) thanks to their low dissipation levels and large subgap resistances.

NanoSQUID are in most cases based on nJJs because nJJs provide the highest critical current density and a better reproducibility in the sub-100 nm size range as compared with three-layer junctions. Description of the operation principle of nJJ can be made according to the theory of (Aslamazov and Larkin, 1968) that is using the Ginzburg-Landau (GL) equation. The GL equation describes Josephson effect in nJJs and it is valid only at temperatures T sufficiently close to the electrode critical temperature T_c : $0.9 T < T < T_c$. In a one-dimensional approximation the GL equation can be written in the form:

$$\xi^2 \frac{d^2 \Psi}{dx^2} + \Psi - \Psi |\Psi|^2 = 0, \quad (3)$$

where ξ is the coherence length and Ψ is the order parameter. When nanobridge length l is shorter than coherence length, ideally $\ell \ll \xi$, the first term dominates and the Eq. (3) is reduced to the Laplace equation $\frac{d^2 \Psi}{dx^2} = 0$, for which the solution is the linear function $\Psi = a + bx$, with x ranging from 0 to l :

$$\Psi = \left(1 - \frac{x}{l}\right) \Psi_\infty + \left(\frac{x}{l}\right) e^{i\Delta\varphi} \Psi_\infty, \quad (4)$$

where $\Delta\varphi$ is the phase difference between the wave functions in the electrodes and Ψ_∞ is the order parameter in the electrodes. Insertion of the latter equation for Ψ into the GL equation for the superconducting current $I_s \sim \text{Im}(\Psi^* \nabla \Psi)$ results in the Josephson current-phase dependence $I_s = I_c \sin(\Delta\varphi)$.

The coherence length diverges at T_c according to the temperature dependence $\xi(T) \propto \left(1 - \frac{T}{T_c}\right)^{-1/2}$ that simplifies the condition $\ell \ll \xi(T)$ for the ideal Josephson effect in nJJs. However, small values of $\xi(0) \leq 10 \text{ nm}$ in the superconducting films of Nb, Pb, NbN, TiNbN, and MoRe with $T_c > 4.2 \text{ K}$ represent a challenge for the structuring of the nJJs using these materials. The current-phase relationship becomes multivalued when the length ℓ of nJJ exceeds the value $3.49\xi(T)$, for example, at temperatures $T \ll T_c$. The

dependence of the maximum superconducting current density J_s on the phase drop $\Delta\varphi$ is described by the Likharev and Yakobson expression:

$$J_s(\Delta\varphi) = \frac{\Phi_0}{2\pi\mu_0\xi\lambda^2} \left[\frac{\xi\Delta\varphi}{l} - \left(\frac{\xi\Delta\varphi}{l} \right)^3 \right]. \quad (5)$$

The $I(V)$ -characteristics of nanoSQUIDs and nJJs made from Nb, Pb, NbN, TiNbN, or MoRe are often hysteretic at 4.2 K due to thermal hysteresis in the nJJs (Skocpol et al., 1974). Usually observed hysteresis of $I(V)$ -characteristics of DC SQUIDs due to Stewart-McCumber parameter $\beta_L > 1$ is unlikely in the case of nanoSQUIDs because nJJs have negligible capacitance when compared with tunnel JJs. The non-hysteretic $I(V)$ -characteristics are required for the use of conventional readout techniques to operate the nanoSQUID as a magnetic flux to voltage converter. In the case of $T \ll T_c$, the $I(V)$ -characteristics become hysteretic, but if the critical current I_c is determined by phenomena of Josephson oscillations, phase-slip, or a creep of Abrikosov vortices it is still possible to use the nanoSQUID for point-by-point measurements of magnetic fields using the dependence of the critical current I_c on the magnetic field that was realized for NbN (Russo et al., 2017) and Nb (Shishkin et al., 2020) nanoSQUIDs. Demonstration of microwave-induced Shapiro steps on hysteretic $I(V)$ -characteristic shows presence of Josephson oscillations in the dissipative branch of such nJJ (Shelly et al., 2020) that can be due to the local overheating of nJJ to the narrow temperature range below T_c where the $I(V)$ characteristics of the nJJs are non-hysteretic. More practical is the realization of non-hysteretic $I(V)$ -characteristics at low temperatures by partial suppression of the critical current using bias magnetic fields ~ 1 T (Anahory et al., 2020). Much below T_c , nJJs in such nanoSQUIDs have a lower Johnson current noise $I_n = (4k_B T/R_N)^{1/2}$, which likely results in lower intrinsic noise and better spin sensitivity of the nanoSQUID. In the case of the potential application of nanoSQUIDs for quantum computers at temperatures ~ 10 mK influence of quantum fluctuations on the operation of nanoSQUIDs cannot be neglected. At temperatures below ~ 100 mK the quantum fluctuations would lead to saturation of the noise on the level $S_{\Phi_Q}^{1/2} = \sqrt{\hbar L_S}$, where L_S is the nanoSQUID loop inductance.

Thermal hysteresis is a result of overheating of nJJ when its superconducting current exceeds the critical current and the dissipated energy will heat the nJJ above T_c so that the nanobridge enters the normal conducting state (Skocpol et al., 1974). The resulting Joule heat dissipated by the normally conducting nanobridge raises additionally its temperature, which in turn reduces the retrapping critical current I_r . The ratio of I_c and I_r depends on the thermal coupling between nJJ and the substrate and it is larger in the case of poor heat removal (for example, in the case of free-standing nJJs or nJJs on membranes). The pure thermal hysteresis is observed at a bias current of the order of depairing current of superconducting film that is typically greater than the sum of the critical currents of nJJs in nanoSQUID does not depend on the magnetic flux through the nanoSQUID loop and therefore cannot be used to measure magnetic fields (Faley et al., 2022).

Eq. (4) is an approximation in which the entire change in the phase of the wave function occurs inside the nJJs. This is a simplified theoretical model that is not suitable for Dayem-type nJJs consisting of electrodes and a nanobridge of the same thickness: the spatial phase change propagates inside the electrodes, almost doubling the effective length of the nJJ (Faley et al., 2021a). A much better approximation to the theory is realized in a variable-thickness nJJ that include a nanobridge thinner than its electrodes. A 3D design of nJJs and nanoSQUIDs using a multilayer technology were successfully realized (Chen et al., 2016). Such nJJs also provide the nanoSQUID with a lower kinetic inductance, thereby improving its voltage swings and the spin sensitivity. Realization of variable-thickness nJJs at nanoscale is also possible within the framework of a single-layer technology using many different tricks: (1.) Directed deposition on 3D-shaped substrate that was used, for example, in construction of elegant SQUID-on-tip cantilevers (Vasyukov et al., 2013), (Anahory et al., 2020); (2.) Oblique incidence evaporation through an electron beam resist shadow mask; (3.) Using undercut during isotropic reactive ion etching (Faley et al., 2021b and Faley et al., 2022); (4.) Using different etch times during patterning of nJJs by FIB etching (Faley and Dunin-Borkowski, 2022); (5.) Using different etch rates in open areas and inside narrow slits in electron beam resist ("grooved Dayem nanobridges") (Trabaldo et al., 2019); etc. As an example, Fig. 2 shows SEM image of a 20-nm-wide variable-thickness TiN nJJ with approximately 100 nm thick electrodes recorded at a 45° sample tilt angle. The remains of the electron beam resist were removed with warm acetone heated to 70 °C. The TiN

Fig. 2 SEM image of a 20-nm-wide variable-thickness TiN nJJ recorded at a 45° sample tilt angle. The TiN electrodes are approximately 100 nm thick.

films sputtered at high temperatures in an Ar-N₂ atmosphere on Si substrates show domain epitaxy and have advantages for the implementation in nanoSQUIDs due to their large coherence length >100 nm at 4.2 K and their high corrosion resistance (Faley et al., 2021b).

Spin sensitivity of nanoSQUID' measurement system at sufficiently high frequencies has a white noise spectrum and is determined by: (1.) Johnson current noise i_n of the nJJs (Voss et al., 1980); (2.) Preamplifier noise of the readout electronics; and (3.) Size of the nanoSQUID loop and its distance to the magnetic nanosize dipole. The Johnson current noise of each nJJ has a white spectrum at the level $i_n = (4k_B T/R_N)^{1/2}$, where R_N is the normal state resistance of the nJJs. The total current noise of the nanoSQUID is $I_n = i_n\sqrt{2}$ and the voltage noise $V_n = R_d I_n$, where R_d is the differential resistance of the nanoSQUID at a bias current slightly above the critical current. The intrinsic flux noise of the nanoSQUID is $\sqrt{S_\Phi} \cong V_n/(\partial V/\partial \Phi)$, where the maximum slope of the transfer function $\partial V/\partial \Phi$ in the approximation of sinusoidal $V(\Phi)$ dependence is determined by the expression (Enpuku et al., 1995):

$$\frac{\partial V}{\partial \Phi} \approx \frac{4}{\Phi_0} \frac{I_c R_n}{\left(1 + \frac{2I_c I_c}{\Phi_0}\right)} \exp\left(-3.5\pi^2 \frac{k_B T L_s}{\Phi_0^2}\right). \quad (6)$$

Decrease of temperature below $\sim 0.9T_c$ leads to increase of energy gap in superconducting films reflected in increase of $I_c R_n$ product in the nJJs, increase of I_c and deviation of $V(\Phi)$ dependence from sinusoidal. The $I(V)$ -characteristics of the nJJs approach hysteresis, which manifests itself in an increase in R_d and V_n at a bias current slightly above $2I_c$. In the flux noise $\sqrt{S_\Phi}$ the changes of V_n and $\partial V/\partial \Phi$ partially compensate each other, but the contribution of noise of the readout electronics decreases. By using the SQUID array preamplifier similar to that demonstrated in Hao (2008), it is possible to further reduce the noise of the readout electronics by a factor of more than 10.

In addition to the white noise, the $1/f$ noise is often observed in nanoSQUIDs at frequencies below 10 kHz and associated with critical current fluctuation in the Josephson junctions (see, for example, (Martínez-Pérez et al., 2017) and (Schmelz et al., 2017)).

The magnetic field resolution $B_n = (\partial B/\partial \Phi)\sqrt{S_\Phi} = \sqrt{S_\Phi}/A_{eff}$, where A_{eff} is an effective area of the nanoSQUID. The spin sensitivity $\sqrt{S_n}$ measured using nanoSQUID of radius r placed on the same axis as a magnetic dipol (electron spin) at the distance h from it is given by the equation:

$$\sqrt{S_n} = \sqrt{S_\Phi} \left(1 + \frac{h^2}{r^2}\right)^{3/2} \frac{r}{r_e}, \quad (7)$$

where $r_e = 2.82 \times 10^{-15}$ m is the classical electron radius. At $h < r$ the spin sensitivity $\sqrt{S_n} = \sqrt{S_\Phi} (r/r_e)$. For a better spin sensitivity it is important to make smaller size of nanoSQUID and place it closer to the nanoscale magnetic object. Bulk nanomachining of silicon substrates for nanoSQUID' cantilevers can be performed with submicrometer precision using RIE (Faley et al., 2021a). Fig. 3a and Fig. 3b show scanning electron microscopy (SEM) images of a planar (a) 2 nJJs nanoSQUID that was structured using RIE and (b) 4 nJJs nanoSQUID that was structured using FIB (Faley and Dunin-Borkowski, 2022). Both nanoSQUIDs were placed within (a) 200 nm and (b) 300 nm from the corners of $2 \times 2 \times 0.05$ mm³ cantilevers using FIB and aluminum sacrificial layers. Such nanoSQUID cantilevers belong to NanoElectroMechanical System (NEMS) are a class of devices integrating electrical and mechanical functionality on the nanoscale. In a scanning nanoSQUID measurement system the cantilever can be placed on a quartz tuning fork at a small angle $\sim 10^\circ$ with respect to the surface of the studied magnetic object, while its corner serves as the tip of an atomic force microscope. In this case the distance between the nanoSQUID and surface of the studied magnetic object would be only ~ 10 nm that is much smaller than the sizes of all currently available planar nanoSQUIDs. The nanoSQUIDs are typically fixed on attocube's positioning and scanning stages that allow extremely large specified measurement scanning range up to 5 mm with sub-nm spatial resolution at 4.2 K.

The maximum of the nanoSQUID voltage response on magnetic flux $\partial V/\partial \Phi$ occurs at a $\Phi_0/4$ magnetic flux bias, which corresponds to 1.5 mT for the nanoSQUID shown in Fig. 2a. Such a flux bias can be achieved without an external magnetic field, but with the help of a direct injection of current through the third (middle) electrode of this nanoSQUID. The flux biasing current,

Fig. 3 (a) SEM image of a planar 2nJJs nanoSQUID structured using RIE. (b) SEM image of a planar 4nJJs nanoSQUID structured using FIB. Both nanoSQUIDs were placed within (a) 200 nm and (b) 300 nm from the corners of $2 \times 2 \times 0.05$ mm cantilevers using FIB and aluminum sacrificial layers.

approaching the depairing current in the superconducting film, is necessary because of the relatively small geometric inductance $L_g \approx 0.14$ pH of the part of the nanoSQUID loop between the left and middle electrodes of the nanoSQUID shown in Fig. 3. Such method of the $\Phi_0/4$ flux bias does not work for smaller nanoSQUIDs: to squeeze $\Phi_0/4$ into the nanoSQUID loop of effective area $A_{eff} < (100 \text{ nm})^2$ the required magnetic field $B > \Phi_0/4A_{eff} \sim 50$ mT. The geometric inductances of the nJJs and the nanoSQUID loop become negligible. The kinetic inductance L_k is much larger, but it cannot be used to generate the constant flux bias. Instead, another method does not require external magnetic fields or injection of additional current in the nanoSQUID loop and based on the phase drops at additional nJJs can be used.

An example of the new flux bias method was demonstrated in the self-flux-biased four-JJ-nanoSQUID (Faley and Dunin-Borkowski, 2022). The effect of self-flux-biasing in such nanoSQUID can be explained when all nJJs are still in zero voltage state. Let us consider nanoSQUID with 4 nJJs of which 2 nJJs have each phase drop φ_1 and the smallest critical current I_{c1} while 2 other nJJs have larger cross-sections, each has a smaller phase drop φ_2 and the largest critical current $I_{c2} > I_{c1}$ (see Fig. 4). The optimal phase drop $2\varphi_2$ on the largest nJJs is equivalent to the required flux bias $\Phi_0/4$.

The relation between the net magnetic flux Φ and the phase drops φ_1 and φ_2 across the nJJs is given by the flux quantization equation in the nanoSQUID' loop: $2\varphi_1 + 2\varphi_2 + 2\pi\Phi/\Phi_0 = 2\pi n$, where n is an integer. At the operation conditions $\Phi = \Phi_0/4$ the bias current of the nanoSQUID $I_b = 2I_{c1}$ that means that the phase drop on these nJJs has the maximal for the zero voltage state value $\varphi_1 = \pi/2$. Each of the other two junctions have phase drop φ_2 determined by their maximal current limited by the critical current of the smallest junctions I_{c1} and its critical current I_{c2} : $\varphi_2 = \arcsin(I_{c1}/I_{c2})$. This maximal current is reached at the magnetic flux Φ passing through the loop of the nanoSQUID $\Phi = (\pi/2 - \varphi_2)\Phi_0/\pi$ at $n = 1$. The maximum responsivity point in zero external magnetic field will be when at the magnetic flux $\Phi = \Phi_0/4$: $2\pi/2 + 2\varphi_2 + 2\pi/4 = 2\pi n$, or: $\varphi_2 = \pi/4$ at $n = 1$. This last equation determines in the first approximation the relation between the critical currents: $I_{c2} = I_{c1}/\sin(\pi/4) = I_{c1}\sqrt{2}$. The real optimal critical current I_{c2} is closer to I_{c1} because the geometrical inductances of the nJJs are not zero and should be also taken into account.

Fig. 4 Schematic representation of 4-nJJs-nanoSQUID. Two nJJs with larger critical current I_{c2} and smaller phase drop $\varphi_2 < \pi/2$ are shown by larger crosses.

Fig. 5 NanoSQUID' $V(\Phi)$ dependences measured using a Quantum Design PPMS for different bias currents at 4.2 K. The uppermost curve was measured at the highest bias current and the bottom curve was measured at the lowest bias current.

Using the third electrode for injection of current through one of the largest nJJs will allow modulation of the flux bias via modulation of φ_2 that is much more effective as compared with the modulation of the external magnetic field or the use of current injection into a part of SQUID loop.

Fig. 5 shows the $V(\Phi)$ dependence of a nanoSQUID' that was measured using a Quantum Design Physical Property Measurement System (PPMS) for different nanoSQUID bias currents close to $I_B \cong 2I_c$ at 4.2 K. The uppermost curve was measured at the highest bias current of 30 μA and the bottom curve corresponds to the lowest bias current of 8 μA . The bias current of the lower curve is slightly below $2I_c$, so almost half of the curve is in the zero voltage state. Increasing of the bias current changes shape of the $V(\Phi)$ dependence to sinusoidal and leads to a non-zero voltage bias at all points of the $V(\Phi)$ curves. At the bias current 15 μA the amplitude of the voltage modulation of the $V(\Phi)$ dependence is maximal as well as its derivative $\partial V/\partial \Phi$ at the optimal for operation bias of the flux $\Phi = \Phi_0/4$. By decreasing of temperature the amplitude of modulation increasing due to increase of the $I_c R_n$ product and the derivative $\partial V/\partial \Phi$ is increasing proportionally to the differential resistance R_d but the shape of the $V(\Phi)$ dependence changes from sinusoidal to rectangular and the range of bias currents where there is any modulation of $V(\Phi)$ dependence is decreasing.

NanoSQUIDs are promising sensors for non-destructive and low noise detection of magnetic fields at low temperatures with submicrometer spatial resolution for study of nanoscale magnetism of condensed matter systems and measure any physical quantity that can be converted into magnetic flux. These mesoscopic-scale, low-temperature conditions are of particular interest because they are in a largely unexplored zone between the quantum world and the normal world. NanoSQUIDs can provide readout of magnetic signals of individual nucleons and electrons and track their quantum interactions while creation of tiny magnetic domains and/or magnetic nanoparticles. In the ideal case, the zero voltage and the magnetic field of the superconducting body of the nanoSQUID ensure lossless measurements that do not destroy the quantum state of the examined objects: Cooper pairs within the superconducting body of nanoSQUID acquire a phase shift due to the presence of only a vector potential of the magnetic field, ideally without any dissipation and in a zero magnetic field. The phase change results in the change in the non-linear inductance of the nanoSQUID, which stays in the zero-voltage state without Johnson noise and can be used in a resonant circuit of a parametric amplifier.

The applications of nanoSQUIDs can be divided into two areas: (1.) "Stationary," where nanoSQUID and the object under investigation are fixed relatively each other on the same substrate; (2.) "Scanning nanoSQUID microscopy," where nanoSQUID is fixed on a cantilever near tip of scanning system. The "Stationary" method is the simplest and it is the mostly used now to study, for example, magnetization of ferromagnetic nanoparticles (Martínez-Pérez et al., 2017). The magnetic nanoparticles can be deposited from a very much diluted solution over the nanoSQUID and the magnetic response of one of them that is occasionally fixed in the vicinity of the nanoSQUID or, better, one on the nJJs, is detected by the nanoSQUID. The magnetic nanoparticle can be exposed to different magnetic fields from zero to high fields > 1 T to investigate its behavior, for example, during magnetization of ferromagnetic nanoparticles or to study their high frequency ferromagnetic resonance. The superconductors like Nb, NbN and, especially, $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ have critical magnetic fields $H_{c2} \gg 1$ T. Another nanoSQUID without magnetic nanoparticle as a reference can be placed on the same chip for subtraction of parasitic background signals. To the prospective "Stationary" applications of nanoSQUIDs belong among other things also readout of qubits, ultra-high frequency detection of nanoscale magnetic fields in combination with single photon detection as a trigger and the detectors for the motion of resonators made from NEMS. At low temperatures, NEMS resonators exhibit quantum behavior.

"Scanning nanoSQUID microscopy" is a type of scanning probe microscopy and a method for imaging magnetic fields on a nanoscale using nanoSQUID as a sensor. A nanoSQUID is mounted on a cantilever tip, which is then scanned over a sub-micron distance from the surface of the sample to be measured. The nanoSQUID cantilevers were realized in the form of: (1.) "SQUID-on-tip" 3D configuration of a nanoSQUID deposited at three different tilt angles on apex of a very sharp pipette that was pulled from a hollow quartz tube (Vasyukov et al., 2013; Anahory et al., 2020) or (2.) A "planar nanoSQUID" fabricated using e-beam lithography on a standard Si wafer, which is then nanosculptured so that the nanoSQUID is within ~ 1 μm proximity of the corner of the cantilever that serves as the cantilever' tip (Faley et al., 2021a; Faley and Dunin-Borkowski, 2022). In both cases the cantilever is fixed on a quartz tuning fork that in a Tapping Mode provides a contactless atomic force feedback for the nanoscale proximity of nanoSQUID to the surface of the investigated object. The mainly van der Waals forces acting on the cantilever as the tip approaches the surface cause the amplitude and frequency of the vibration of the tuning fork to change as the tip approaches the sample. Another scanning mode is also possible, similar to that used in the case of a magnetic force microscope: nanoSQUID can scan at a certain distance from the surface of the sample. The sensitivity and spatial resolution will be worse in this case, but this mode will be safer (non-destructive) for both the nanoSQUID and the sample. Any touching of the sample surface poses a risk of destroying nanoSQUID in the SQUID-on-tip configuration, which requires special care during operation. Planar nanoSQUIDs in this case are still at a controlled safe distance from the object and can be used also in Contact Mode.

Key issues

To date, the SQUID-on-tip configuration has demonstrated the possibility to realize the smallest size of nanoSQUIDs ~ 40 nm, and the best spatial resolution ~ 40 nm and the best spin sensitivity of down to < 0.3 $\mu\text{B}/\sqrt{\text{Hz}}$ (Anahory et al., 2020). However, flexibility in choice of superconducting materials and design of nanoSQUIDs, their reproducibility and long-term stability are the advantages of cantilevers with planar nanoSQUIDs that were fabricated by e-beam lithography and nanosculpturing techniques. As an example, Fig. 6a shows a photograph of a 100 mm diameter silicon wafer pre-etched in KOH to fabricate 132 nanoSQUID cantilevers (Fig. 6b). For example, epitaxial growth of nitrides or the high- T_c superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ on molten quartz capillaries would be a problem. The reproducibility of both types of nanoSQUIDs is limited by the relative scatter of the sizes $\delta x/x$ due to local variations of material properties, which strongly increases with decreasing nanostructure size $x < 100$ nm.

Fig. 6 (a) Photograph of a 100 mm diameter silicon wafer pre-etched in KOH to make 132 nanoSQUID cantilevers. (b) Photograph of a $2 \times 2 \times 0.05$ mm cantilever with a nanoSQUID placed on an ordinary match as a scale.

The long-term stability of nanoSQUIDs is an important issue related to the corrosion resistance of the superconducting materials used. Up to ~ 10 nm nanometers from the surface of Nb are oxidizing very fast but exactly such thickness would be optimal because the coherence length in Nb films is ~ 10 nm. Moreover, niobium films react with water and oxygen in laboratory air: in columnar-grown polycrystalline films of niobium oxygen penetrates along grain boundaries through the whole film and produces Nb_2O_5 crystallites that expand and crack the Nb films and the nJJs. Pb films are unstable to degradation during thermal cycling from room temperature to an operating temperature of 4.2 K: this leads to the formation of bumps and cavities on the films, which also destroy the nJJs. Films of the high-temperature superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ decompose in air with the formation of carbonates.

Various methods of film surface passivation are used with varying degrees of efficiency. Coating of Nb films by a protective layer of NbN significantly suppress their oxidation: NbN is resistant to O_2 , H_2 , CO_2 , and air. The passivating Si protective layer improves heat dissipation and protect against the mechanical and electrical fragility of the devices: prevents nJJ from being destroyed by electrostatic discharges. Devices made from $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ films usually require vacuum-tight encapsulation or can be partially protected by epitaxial films of SrTiO_3 .

Epitaxial films of TiN and NbN nitrides have excellent corrosion resistance, which contributes to the long-term stability of nJJ and nanoSQUID. Unlike NbN films, TiN films have only recently begun to be used to fabricate nJJ and nanoSQUID. Thanks to the large coherence length $\xi(0) > 100$ nm at 4.2 K of the TiN films, the non-hysteretic variable-thickness TiN nJJs were realized using e-beam lithography and reactive ion etching. The TiN nJJs with smaller cross-section operate at mK temperatures and can be combined with high quality resonators made from the same material. Multilayers of NbN/TiN have even better mechanical, anticorrosion, and superconducting properties when compared with single-layer NbN and TiN films. MoRe is another corrosion-resistant superconducting material that has been used for the preparation of nanoSQUIDs. Thin films of NbN and MoRe have relatively large energy gaps $2\Delta \sim 5$ meV. However, their T_c values of up to ~ 16 K and their very short coherence lengths ξ of ~ 5 nm lead to difficulties in the realization of non-hysteretic nanoSQUIDs with nJJs at an operation temperature of 4.2 K. A combination of TiN nanobridge with NbN electrodes was realized using a double layer of NbN/TiN, so creating an S-S'-S nJJ, where the S' superconductor TiN has $T_c \leq 6$ K that is smaller than T_c of the S superconductor NbN. By optimization of deposition parameters and relative thickness of these nitride superconductors it is possible to optimize the superconducting parameters of the corrosion resistant nJJs and nanoSQUIDs.

Conclusion

The fabrication methods, principle of operation, microstructural and electron transport properties, as well as the application of nanoSQUIDs are considered. NanoSQUIDs by definition have a submicrometer loop size, which limits dimensions of Josephson junctions to about 100 nm or less. This makes the use of tunnel junctions problematic, but encourages the use of nanobridges and other types of nJJs with high critical current densities. The use of nitride superconductors helps to optimize the superconducting parameters and enhances the corrosion resistance of the Josephson junctions and nanoSQUIDs. Additional passivation by, for instance, an amorphous Si layer can improve thermal sink of the nJJs and protect against the mechanical and electrical fragility of the devices. Nanosculpturing of cantilevers makes it possible to position the nanoSQUID at a distance of 10–100 nm from the objects under study in the nanoSQUID scanning system. Several promising applications of nanoSQUIDs are briefly reviewed.

With the development of research and applications in mesoscopic quantum systems ("nanoworld"), nanoSQUIDs will play an important role in their niche of low-temperature low-noise measurements and detectors. Planar nanoSQUIDs should reach spin

sensitivities that were so far demonstrated only in SQUID-on-tip 3D configuration. The reproducibility, long-term stability of planar nanoSQUIDs, and the possibility of their fabrication on standard silicon wafers in large quantities should facilitate their market acceptance and mass production by commercial companies. Ideally, cantilevers with nanoSQUIDs should become as accessible as cantilevers for atomic force microscopes. The submicron distance between the nanoSQUID and the tip of the cantilever should be the standard. The tip can be a cantilever corner or a pin that can be grown on the surface of the cantilever, for example, by local electron beam assisted carbon, tungsten or platinum deposition inside the SEM or FIB.

The issues of structuring thin films of various superconducting materials for nanoSQUIDs are being further developed. So far, nanoSQUIDs were realized with Nb, NbN, Pb, $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, MoRe, MgB_2 , doped diamond, Ti, and TiN. The variety of superconducting materials used in the nanoSQUIDs matches the many different applications in which these nanoSQUIDs will be used. For example, nanoSQUIDs designed to measure the magnetization of nanoparticles must be able to operate in strong magnetic fields $H_{c2} > 1$ T that corresponds to superconducting coherence length $\xi < 18$ nm. Films of Nb ($\xi(0) \cong 10$ nm), NbN ($\xi(0) \cong 6$ nm) and $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ($\xi(0) \cong 1$ nm) satisfy this criteria. NbN-based nanoSQUIDs have demonstrated sustainability to fields below 8 T parallel to the plane of the nanoSQUID's loop. The theoretical estimate of the corresponding coherence length $\xi \sim \sqrt{\frac{\hbar}{2e\mu_0 H_{c2}}} \sim 6$ nm is well suited for the NbN films. If a strong magnetic field is not essential, a more comfortable operating temperature of 4.2 K can be realized using TiN films. With the help of TiN films, it is also possible to realize completely TiN nJJ for qubits and their readout based on nanoSQUIDs operating at temperatures of ~ 10 mK thanks to the large coherence length ξ_{TiN} in TiN films and possibility to create TiN-nJJs of a size much smaller than ξ_{TiN} . In this case, the temperature dependence of the critical current TiN nJJ saturates at low temperatures (Faley et al., 2022), similarly to the temperature dependence of tunneling Josephson junctions.

New promising potential applications for planar and/or 3D nanoSQUIDs are expected to be developed. To give just a couple of examples, nanoSQUIDs can be also used in: (a) cryogenic transmission electron microscopes (Cryo-TEM) and (b) for reading the results of calculations of adiabatic quantum annealing in arrays of quantum bits using a nanoSQUID scanning system:

(a) TEM sample holders cooled with liquid nitrogen or helium are now commercially available. Superconducting nanostructures, such as narrow lines or Josephson junctions in the form of nanobridges, are quite thin and can be fabricated on electron transparent SiN membranes for use in TEM. Superconducting circuits have extremely low energy dissipation, which is of great advantage when they operate on a thin membrane under ultrahigh vacuum TEM conditions. Josephson radiation from nJJ can be used to excite magnetic resonances in magnetic nanoparticles or coplanar lines, while nanoSQUIDs can detect their net magnetization.

(b) Quantum calculations based on adiabatic quantum annealing lead to a two-dimensional distribution of magnetic moments stored in individual quantum bits in their final classical (non-entangled) mode. The reading of these results can be performed non-destructively using the nanoSQUID scanning system and clearly represented in the form of a 2D magnetic image. This would drastically reduce number of wires needed for operation of superconducting quantum computer. Exposure of the nJJs to FIB can provide controlled suppression of their T_c and this can help optimize the operation of nanoSQUIDs at the millikelvin temperatures.

Abstract

Van der Waals heterostructures formed by mechanically stacking layers of 2-Dimensional (2D) materials possess unique properties and new functionalities, not seen in standard materials, that make them an irreplaceable platform for emergent electronics. What hinders the progress in utilizing van der Waals' attractive features in technology is the fact that many of them, especially the novel topological quantum states and related phenomena, are restricted to low temperatures. This poses the challenge of creating van der Waals heterostructures harboring novel topological quantum matter physics at elevated temperatures. This challenge is met by employing high-temperature superconductors-based 2D films, which offer the most advantageous route to increase the temperature range in which the topological states and phenomena associated with van der Waals devices can be used. Realizing this daunting task requires understanding the microscopic mechanisms underlying their properties as well as the developing technologies for their engineering and manipulation. This article addresses the use of $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{4+2n+x}$ films. Its chemical complexity is analyzed by studying the role of the oxygen dopants and incommensurate lattice modulation, which is a key element for understanding the electrical properties of cuprates. Utilizing solvent- and polymer-free nanofabrication advances makes it possible to create Josephson junctions based on high-temperature superconductors. This article describes the fundamental properties of such a junction and discusses the possibility of introducing twisted high-temperature superconductors in quantum circuits.

Key points

- An introduction to the state of quantum technologies and challenges is given.
- Complexity of the cuprate materials is reviewed by giving special attention to the role of the oxygen ordering and the incommensurate superlattice modulations.
- Fabrication methodologies for the realization of van der Waals twisted cuprate heterostructures are reviewed. Special attention is given to the cryogenic stacking technique.
- Topological superconductivity in twisted cuprate heterostructures is introduced.
- A prospective outlook for the microwave quantum circuit integration in twisted cuprate heterostructures is given.

Introduction

Quantum mechanics is a fundamental theory in physics that explains phenomena found in nature at the scale of atoms and subatomic particles. Modern technologies operate at a scale where quantum effects like quantum entanglement (Horodecki et al., 2009), quantum superposition, and quantum tunneling are significant. For this reason, in the last few decades, an emerging field of physics and engineering encompassing technologies that rely on the properties of quantum mechanics is born. Understanding the laws of quantum physics in order to build new and exciting applications is the purpose of Quantum Technology. Famous examples of emerging quantum technologies are quantum computing (Gyongyosi and Imre, 2019), sensors (Degen et al., 2017), cryptography (Pirandola et al., 2020), and simulation (Georgescu et al., 2014). These technologies are studied today in laboratories all over the world and are waiting to be turned into applications, marking the beginning of a second quantum revolution (Durakiewicz and Greene, 2018). The development of these kinds of quantum technologies will in fact heavily impact established fields like cybersecurity, financial modeling, machine learning, and pharmaceutical and chemical industries. In order to create such a

revolution, manifold platforms have been developed because there is no ubiquitous way to exploit the properties of quantum physics to build quantum devices. Ultra-cold atoms (Langen et al., 2015), ion traps (Bruzewicz et al., 2019), and photonics (Slussarenko and Pryde, 2019) are just a few examples of the possible ways to build quantum applications. However, one of the most promising platforms that are mostly used in the world of quantum devices is superconductivity.

In these last years, a lot of successes have been achieved exploiting the properties of superconducting materials, and some of their technological applications include sensitive magnetometers (superconducting quantum interference device) (Fagaly, 2006), fast digital circuits like rapid single flux quantum (RSFQ) technology (Bunyk et al., 2001), Qubits (Kjaergaard et al., 2020), high sensitivity particle detectors like kinetic inductance detector (mKID) (Ulbricht et al., 2021), and superconducting nanowire single-photon detector (SNSPD) (You, 2020). Nevertheless, even if the achievements of the superconductive devices are impressive and their performances are surprising, it is also true that the materials employed are monoatomic, like Niobium or Germanium, or at most diatomic like AlO (Kjaergaard et al., 2020; Scappucci et al., 2021). Then, currently, the activities regarding superconductivity rely on these materials which become superconductive at temperatures far below ambient (T_c of a few Kelvin) and therefore require elaborated cooling systems. On the other hand, high-temperature superconductors (HTSs) show a higher resistance to more “disadvantage conditions” for superconductivity like higher critical temperature and pressure. However, high-temperature superconductivity, under pressure ambient conditions, cannot be achieved with monoatomic or diatomic materials. It has already been shown that the lattice complexity plays a key role in defining the critical temperature of a superconductive material (Poccia et al., 2012b). In fact, the critical temperature increases with the number of atomic elements in the lattice proving that HTSs require an intrinsic complexity of the lattice and consequentially of the phase diagram (Keimer et al., 2015; Poccia et al., 2010). This realization initiated new efforts with respect to material science, which has developed into fascinating fields of research and has discovered several families of HTS.

A remarkable and promising class of HTSs are the cuprate families (Bednorz and Müller, 1988; Chu et al., 2015), called like that since CuO_2 (cuprous oxide) plane is the common component in all these new HTS. Common traits of all the cuprates are their layered structure, consisting of CuO_2 layers separated by insulating layers, and the difficulty to handle them due to their ceramic nature. There are five main classes of superconducting cuprates: lanthanum-based, yttrium-based, bismuth-based, thallium-based, and mercury-based. A special place in the cuprate families is held by the bismuth-based compound Bi-Sr-Ca-Cu-O (Fig. 1), which is held together by van der Waals (vdW) bond in between BiO layers and can be realized in three crystallographic phases, Bi-2201, Bi-2212, and Bi-2223, forming a homologous series as $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{4+2n+x}$ with $n = 1, 2$, and 3 , each one of them with different superconducting critical temperature properties.

The unique nodal Fermi surface investigated with a variety of spectroscopic techniques (Saleem and Hussain, 2013) and the emerging strange metallic properties (Božović et al., 2017), different from those of monoatomic and diatomic superconductors, not only have made these Bismuth-based cuprates important for our fundamental understanding of HTSs, but are also considered as key advantages for future circuit quantum electrodynamics (cQED) in HTSs. In the later sections, the BSCCO vdW heterostructures and properties are introduced. Finally, the perspective and flexibility of these heterostructures in the field of superconductive technologies are discussed.

Van der Waals nature of high-temperature superconductors and their chemical complexity

Practical applications of HTSs are steadily improving every year and count a variety of systems going from the large scale (e.g., superconducting bearings for motors, fault current limiters for energy storage devices) (MacManus-Driscoll and Wimbush, 2021) to the small scale (e.g., superconducting quantum interference devices for magnetometry, superconducting and bolometers for astronomy) (Stornaiuolo and Tafuri, 2019). Grain Boundaries (GBs) have been used to create JJs in cuprate HTSs and have had a significant impact on our understanding of the macroscopic properties of these complex materials (Hilgenkamp and Mannhart, 2002). One of the main experimental evidence of oscillatory supercurrent density following a d-wave pairing symmetry was found in biepitaxial GB made of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ (YBCO) HTSs (Lombardi et al., 2002). A conclusive proof for the d-wave order in HTS JJs was demonstrated in tricrystal ring experiments with YBCO (Tsuei et al., 2004). Here the GBs angles were adjusted so that one segment could show a π phase shift with the consequence that a spontaneous circulating current could be detected by scanning quantum interference device microscope images. However, GBs interfaces can only be realized in-plane and can form multifaceted interfaces that may result in unusual magnetic interference patterns and spontaneous flux generation (Hilgenkamp et al., 1996). Moreover, the predicted quasiparticle suppression (important for quantum hardware, Kawabata et al., 2004) in vertical JJs near 45 degrees cannot be realized in in-plane GBs JJ. Although experimental evidence pointed out that quantization of JJs might be possible in YBCO GBs, enabling the prospect for quantum devices using these systems, the same author pointed out that improvement of the interface is necessary to fully exploit HTS in quantum hardware (Bauch et al., 2006).

In recent years, an alternative road exploits the isolation of atomically thin Bi-2212 vdW crystals without degrading the superconducting transition temperature compared to bulk crystals (Yu et al., 2019; Zhao et al., 2019). This experimental progress has encouraged theoretical predictions for a second-order co-tunneling effect in twisted Bi-2212 bilayers, facilitating a coherent superposition of d-wave orders (Can et al., 2021; Volkov et al., 2020). The energetically favorable configuration is characterized by a finite superconducting gap for all momenta, and more importantly, corresponds to a phase with a spontaneously broken time-reversal symmetry (TRS) (Volkov et al., 2021; Tummuru et al., 2022b; Song et al., 2022). Employing HTSs based on 2D films for manufacturing vdW heterostructures, therefore, offers the most advantageous route to increase the temperature range in which the topological states and phenomena associated with vdW devices can be studied and used.

However, stacking Bi-2212 is a great challenge, and many attempts have been realized over the years. Previously, Bi-2212 twist junctions required high-temperature oxygen annealing to restore interfacial superconductivity (Li et al., 1999; Latyshev et al., 2004; Zhu et al., 2021; Takano et al., 2002; Lee et al., 2021), often at the cost of a significant interfacial structural reconstruction, suppressed T_c , low critical current density J_c at zero twist angle, and pronounced anomalies in the resistance–temperature $R(T)$ curves. In the coming subsections, we will discuss the origin and the role of the oxygen and the complexity in the fabrication of mesoscale devices based on thin cuprate crystals.

The role of oxygen dopants in cuprates

The structure of bulk Bi-2212 (BSCCO), as presented in Fig. 1A, consists of alternately stacked superconducting CuO_2 bilayers, and insulating SrO-BiO layers. This insulating layer creates a tunnel-type Josephson coupling between two superconducting CuO_2 bilayers and this special atomic arrangement determines the intrinsic Josephson coupling in between the layers experimentally measured (Kleiner et al., 1992; Yurgens, 2000). The coexistence of such high T_c (nitrogen temperatures) at ambient pressure and at the same time naturally forming intrinsic Josephson junctions along the c -axis already is enough to make the BSCCO unique among the cuprate materials, but more generally among all the HTSs families. The wonder and complexity of the BSCCO materials are well visible by looking also at the structure.

The differences between CuO_2 layers and the insulating layers indeed give rise to intriguing crystallographic patterns up to the mesoscale, which can control superconducting properties (Bianconi et al., 1998; Gao et al., 2009; Triscone et al., 1990; Yamamoto et al., 1990). The percolative process has subtle effects in the superconducting properties of the system, determined by a spatial interplay between k -space and r -space orders as probed by several experiments and discussed in theory works (Fratini et al., 2010; Campi et al., 2015; Poccia et al., 2014a, b; De Mello and Dias, 2007; Pelc et al., 2019; Kugel et al., 2008). Furthermore, BSCCO, as a cuprate superconductor, displays startling nanoscale inhomogeneity in essential properties such as the spectral gap (Howald et al., 2001; Pan et al., 2001) and the pairing temperature (Gomes et al., 2007). Lattice strains control this electronic inhomogeneity since they have been empirically linked with electronic structure. The largest source of strain in Bi-2212 is an incommensurate structural buckling (see Fig. 1B) known as the ILMs (Petricek et al., 1990; Le Page et al., 1989). The 1D incommensurate modulation has been recently modeled as mismatched CuO_2 bilayers (Sboychakov et al., 2022). The authors here intriguingly point out the remarkable similarity of the complex Van Hove Singularity (VHS) splitting with VHS due to the moiré lattice as it is in strained twisted bilayer graphene. A tiny variation in the oxygen disposition in the ILM may change the Fermi level at these VHS, dramatically changing the properties of the system. The ILM along the b -axis in BSCCO is known experimentally to produce weak-diffuse and sharp-intense satellite diffraction peaks up to high temperatures (Castellan et al., 2006; Izquierdo et al., 2006; Comes et al., 2007) and it is correlated with the distribution of oxygen interstitials in the SrO (Zeljko et al., 2014, 2012b) and BiO layers (Zeljko et al., 2012a). Furthermore, ILM is also correlated with the Fermi surface reconstruction (Valla et al., 2019), and the inhomogeneous

distribution of the ILM can change the spatial variation of the superconducting gaps (Slezak et al., 2008) and percolative electronic orders (Carlson and Dahmen, 2011; Carlson et al., 2015).

The previous discussion should therefore make clear to the reader that BSCCO is a complex material and in order to integrate it in mesoscale devices novel methodologies of fabrication are required. Indeed, the methodologies of fabrication need to be developed in order to keep the complexity of the BSCCO intact, especially for what concerns the r - k space orders of oxygen dopants. To get a glimpse of this complexity, the reader is referred to the STM studies, which can be used to analyze the dopants' arrangements in BSCCO highlighting that the oxygen dopants are periodically distributed in correlation with local strain. There are two sources of strain: the previously introduced incommensurate lattice modulation known as the "supermodulation" and the commensurate orthorhombic distortion that shifts two sublattices in opposite directions primarily in the BiO plane (Zeljko et al., 2012a; Subramanian et al., 1988). On the other hand there are three species of dopants:

- The interstitial oxygen dopants called "type-A," which are likely to be in the SrO layer (Zeljko et al., 2012b; Zhou et al., 2007).
- The interstitial oxygen dopants called "type-B," which are likely to be in the BiO layer (McElroy et al., 2005).
- The apical oxygen vacancies, which are thought to donate electrons to the CuO₂ plane (Zeljko et al., 2012b).

Then the STM can locate the three species of dopants with picoscale precision in Bi-2212. In particular, it turns out that the type-B oxygen dopant and the apical oxygen vacancies are correlated with the supermodulation, suggesting the potential utility of the supermodulation as a scaffold for such dopant arrangements. Furthermore, this expresses the importance of oxygen dopants in cuprates because the gap is locally controlled by dopants alone.

As previously mentioned, the superconducting properties are therefore retained only if the configuration of the oxygens is intact after any fabrication process. Nevertheless, the oxygens present high mobility at temperatures higher than 200 K (Poccia et al., 2011b, 2012a; Littlewood, 2011). In this experiment, it is shown that oxygen can be regulated by X-ray light in staged, ordered structures only above 200 K and below 300 K. However, the X-ray continuous manipulation of the cuprate material is not possible anymore if the temperature is below 200 K because below this temperature the oxygens are frozen and the X-ray exposition cannot induce the ordering of the oxygen interstitials. Furthermore, the volatility of oxygen interstitials in the crystals increases as the thickness is decreased and as a result, the lattice becomes more unstable. Given that most of the cuprates are oxygen ion conductors (Skinner and Kilner, 2003), thin BSCCO crystals reduce the thermal activation gap of the oxygen interstitials, which become freer to roam in the lattice. However, oxygen interstitials diffusion can also introduce cracks in the lattice and therefore detrimental disorder in the system. One of the main goals in device technology with BSCCO is therefore to slow down the deterioration of the flakes during the nanofabrication. But the oxygens are not the only factor to consider because, although it has been observed that some layered materials are vertically bonded together by weak vdW bonds that can be cleaved by a simple scotch tape exfoliation, the softness and structural modulation nature of the compound make the synthesis of the ultra-thin film of BSCCO a real challenge (Sandilands et al., 2014). The early attempts to stamp the BSCCO crystal on a substrate using a scotch tape indeed produced atomically thin crystals that were, unfortunately, insulating (Novoselov et al., 2005).

By analyzing the principal properties in the bulk BSCCO using micro X-rays (Poccia et al., 2011a), one may wonder if these properties, including ILM, would change in the 2D limit since the elastic properties of the atomically thin crystals can differ from those in the bulk (Poccia et al., 2020) due to the higher elasticity of thin crystal compared with the bulk. The answer lies in the comparison of the ILM in the bulk BSCCO crystal and a thin film of BSCCO (Fig. 2). This can be done using the X-ray diffraction technique. In particular, the spatial distribution of the ILMs can be visualized using X-ray diffraction at the bulk (Yamamoto et al., 1990; Bianconi et al., 1996; Castellan et al., 2006; Izquierdo et al., 2006). Using this technique, the 1D ILM has been reported to have both diffuse short-range order (SRO) satellites and long-range order (LRO) satellites around Bragg peaks.

The experiment shows that the incommensurate lattice modulation distribution forms puddles of different wavevectors in real space for the bulk crystal. As the crystal is reduced down to 6 nm of thickness, the wavevector of the incommensurate lattice modulation remains basically constant, with some minimal variation in real space given that the thin flakes were realized at room temperature and the system was, therefore, more unstable. Indeed, the puddles spatial correlation changes in the atomically thin limit even in the case the fabrication is realized in an inert atmosphere and the system is encapsulated. The puddles organization has a subtle influence on the electronic properties of the system (Velasco and Neto, 2023; Tromp et al., 2023) and its synchronization. The lattice degradation is observed also in transmission electron microscopy pictures (Zhao et al., 2019) even though the superconductivity in the same arrangement of the materials was preserved down to the atomically thin limit and the Hall-effect measured with the advanced methodology of the stencil mask applied in inert environment and metallic evaporation performed in situ. It is therefore made apparent from these measurements that a 0.5 u.c. of the surface of any BSCCO crystals is extremely complex to preserve and keep intact during a fabrication process. An encouraging result showed that 0.5 u.c. crystals can be realized and superconductivity preserved intact if the BSCCO crystals are exfoliated below room temperature and the electrical contacts realized cold (Yu et al., 2019). Both the Hall measurements in atomically thin BSCCO (Zhao et al., 2019) and the 0.5 u.c. BSCCO superconductor (Yu et al., 2019) had clear advantages and disadvantages in terms of fabrication. Both the experiments nevertheless showed that atomically thin BSCCO crystals were indeed superconducting, setting up the stage for the search of new methodologies in order to integrate the advantages in fabrication discovered in Zhao et al. (2019) and Yu et al. (2019) in new fabrication procedures, which could enable more complex mesoscale devices with atomically thin BSCCO crystals. These are the topics of the next two sections.

Fig. 2 (A) Schematic diagram of the scanning nano X-ray diffraction of a BSCCO bulk single crystal. The diffracted beam is collected by a 2D detector whose image is integrated from a wide-range angular scan. (B) The probability density function of δk is calculated from the LRO and SRO maps. Furthermore, in order to characterize and map the lattice strain, the wave-vector fluctuations δk for the [002] Bragg peak have been plotted. The experimental resolution is indicated by the shadowed rectangle. (C) Scanning nano X-ray diffraction of a thin vdW BSCCO heterostructure. (D) Probability density function of δk calculated from the LRO, the SRO, and the [002] peak maps of the thin film. In this case, the variation of the [002] peak exceeds the experimental resolution. Adapted from Poccia N, Zhao SYF, Yoo H, Huang X, Yan H, Chu YS, Zhong R, Gu G, Mazzoli C, Watanabe K, Taniguchi T, Campi G, Vinokur VM, and Kim P (2020) Spatially correlated incommensurate lattice modulations in an atomically thin high-temperature $\text{Br}_{2.1}\text{Sr}_{1.9}\text{CaCu}_{2.0}\text{O}_{8+y}$ superconductor. *Physical Review Materials* 4(11). <https://doi.org/10.1103/physrevmaterials4.114007>.

Twistronics of $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{4+2n+x}$

But there is more to the BSCCO. The terminating layer is an insulating BiO layer, and usually mechanical cleavage occurs between BiO double layers (see Fig. 1B) due to the weaker vdW bonding (Shaw et al., 1988; Sunshine et al., 1988; Tarascon et al., 1988). For this reason, as introduced in the previous section, the BSCCO can form a tunneling junction along the c -axis without the insertion of an insulating layer. Previous experiments on twisted Bi-2212 can be categorized based on the starting crystals used to construct the junction (Li et al., 1999; Latyshev et al., 2004; Zhu et al., 2021; Takano et al., 2002). One experiment utilized bulk single crystals—the only experiment to match the bulk T_c . Structurally, the crystal layers next to the twist junction interface were thicker than the rest and were identified as $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+x}$ (Bi-2223) layers (Li et al., 1999). However, due to the large twist interface area, accurate measurements of the coupling between crystals were difficult, and no angular dependence was observed. Two experiments relied on Bi-2212 whiskers, either placed atop one another or naturally fused during growth (Latyshev et al., 2004; Takano et al., 2002). In both cases, the interfaces had to be annealed at 850°C to become superconducting. The resulting devices had a high T_c (~73 K vs. 65 K) and a critical current density J_c (1.17 kA/cm² vs. 0.05 kA/cm²). However, even in these high-quality junctions, structural reconstruction was visible. The second crystal layer from the interface appeared to be 22% thinner than the rest, and the junctions' Fraunhofer patterns were poorly defined. The Shapiro step at 45 degrees also showed integer steps.

In all these experiments, the crystallinity and chemical composition of the surface forming the twist junction are uncontrolled due to air exposure and/or the whiskers' growth environment. From the experience with atomically thin Bi-2212 crystals, however, it became clear that the resulting junction is no more superconducting after a brief (~10 minutes) exposures to air, even when covered by boron nitride crystals (Zhao et al., 2019; Yu et al., 2019). So, it is not surprising that the re-annealed twist interfaces in these experiments are structurally distinct from the bulk.

Among the experiments using vdW fabrication techniques, one method involved cleaving the crystals in argon at 100–200°C and exfoliating the two copies without touching the interface area (Zhu et al., 2021; Lee et al., 2021). The molten transfer polymer had to be subsequently washed off in acetone. In contrast, in another experiment, researchers exfoliated their crystals onto Gel-Pak polymer stamps (Lee et al., 2021) and placed two crystals atop one another onto pre-patterned electrodes to form the twist junction. This procedure was done at room temperature and in argon, but Gel-Pak is known to leave visible residues in optical microscopes, and this polymer stamp was placed directly in contact with the bottom crystal's interfacial region. Furthermore, twist junction transport characteristics often degrade when the interfacial region has been exposed to argon for more than a few minutes as it happens for a 0.5 u.c. atomically thin Bi-2212 crystal. Therefore, the junctions required annealing before becoming superconducting. However, even after the annealing procedure, the contributions reported a prominent structural reconstruction at the interface, a prominent two-step superconducting transition versus temperature, and a large spread in both T_c (<60 K at best) and J_c (smaller than intrinsic JJs values). In this regard, an alternative approach for transferring atomically thin Bi-2212 crystals has been developed based on a cryogenic pick-and-place technique used to create intrinsic JJs (Zhao et al., 2019; Lee et al., 2023; Martini et al., 2023).

This technique consists of cleaving a sequential pair of fresh surfaces of the Bi-2212 from a pre-exfoliated single crystal and stacking the two resulting flakes on top of each other. First, the Bi-2212 crystals are mechanically exfoliated with scotch tape on SiO₂/Si substrates. Next, we cover the Bi-2212 flake with an edge of a PDMS stamp placed on a glass slide (mounted on a micromanipulator), and we let the assembly thermalize. At a temperature slightly above the glass transition of PDMS ($T_g = -120^\circ\text{C}$), the stamp becomes very adhesive. By quickly detaching the stamp from the substrate, we can cleave the crystal along an atomically flat plane between BiO planes, obtaining two thinner flakes. The flake standing on the PDMS stamp is aligned and placed back onto the bottom flake on the substrate within 90 s. The time between cleaving and stacking makes a big impact on the junction's quality.

Finally, the stage is slowly heated up to -30°C and the top flake is released on the bottom one (the PDMS loses its adhesive properties). The control over the adhesion of the PDMS stamp allows us to fabricate the junctions using a dry and solvent-free transfer at low temperatures. Additionally, the interfaces can be protected from water molecules by placing an encapsulating hexagonal boron nitride (hBN) flake on top of the stacked flakes immediately after stacking. This improves the interfaces' survival when they are transferred to a cryogenic measurement system (Lee et al., 2023; Martini et al., 2023). Electrical contacts can be deposited in two steps using a chemical-free stencil mask technique in an evaporation chamber, directly connected to the glovebox cluster. The T_c of the JJs is close to that of a bulk crystal, indicating the high uniformity of oxygen dopants. In Fig. 3, there is a sketch of a single flake cleaved by the sticky PDMS stamp.

Josephson effects in twisted Bi₂Sr₂Ca_n-1Cu_nO_{4+2n+x}

Exploiting this fabrication process is possible to create a two-dimensional BSCCO assembled into bilayers with a twist between individual layers. In Fig. 4A, an example of 42.6 degrees twisted junction is reported. Measurements of Current-voltage characteristics and normalized differential resistance are presented in Fig. 4B.

The twist angle modulates interfacial Josephson coupling between twisted nodal d-wave superconductors (Klemm, 2005). At exactly $\theta = 45$ degrees, only the second-order co-tunneling of Cooper pairs is allowed (Can et al., 2021; Sigrist, 1998; Goldobin et al., 2007) while direct Cooper pair tunneling is forbidden due to the complete mismatch between the $d_{x^2-y^2}$ symmetric superconducting order parameters (SOPs) across the interface (Klemm, 2005). This is expected to support topological, time-reversal symmetry-breaking superconducting phases persisting up to the junction superconducting transition temperature T_c (Can et al., 2021; Yang et al., 2018). At $\theta = 0$ degree, electronic characteristics similar to single-crystal intrinsic junctions are shown by the BSCCO junction (Zhao et al., 2021; Lee et al., 2023, 2021). The encapsulation is realized to prolongate the lifetime of the junctions in ambient conditions, moreover, it becomes essential in order to realize intrinsic junctions if the thermal evaporation of the electrical contacts is done in a high vacuum chamber (10^{-6} bar) (Lee et al., 2023; Martini et al., 2023) in comparison to a more

Fig. 3 A polymer called polydimethylsiloxane is used to exfoliate a BSCCO crystal at -90°C . The stacking process of a BSCCO flake on to another is done at -90°C because as previously mentioned, the oxygens are frozen under 200 K preserving the ILM and the electronic properties. The interface creation is done therefore in less than one minute with each flake oriented to each other at the desired angle.

Fig. 4 (A) Optical micrographs of a twisted JJs device with a twist angle of 42.6 degrees. (B) Current–voltage characteristics of JJ are measured by sweeping the current at different temperatures. In the insert the normalized differential resistance $[dV/dI]/R_N$ as a function of $I_C R_N$ and temperature T from 2 to 80 K has been shown. The lowest values of the normalized differential resistance are *black* while the highest values are *yellow*. Adapted from Lee Y, Martini M, Confalone T, Shokri S, Saggau CN, Wolf D, Gu G, Watanabe K, Taniguchi T, Montemurro D, Vinokur VM, Nielsch K, and Poccia N (2023) Encapsulating high-temperature superconducting twisted van der Waals heterostructures blocks detrimental effects of disorder. *Advanced Materials* 35(15): 2209135. <https://doi.org/10.1002/adma.202209135>.

expensive ultra-high vacuum evaporator (10^{-8} bar) (Zhao et al., 2021). These experimental observations indicate that for $\theta = 0$ degree the JJ reaches electronic quality comparable to intrinsic JJ in single-crystal BSCCO as observed in bulk crystals (Kleiner et al., 1992). Normalizing the bias current with the junction normal resistance R_N , the transport characteristics of different twisted JJs can be compared. Since I_C and R_N^{-1} are proportional to the area of the junction, the product $I_C R_N$ is independent of the junction area. It comes out that the magnitude of $I_C R_N$ becomes smaller closer to 45 and 135 degrees where the JJs also appear less hysteretic (Zhao et al., 2021). In particular, $I_C R_N(\theta)$ has a behavior similar to the angular dependence of junction voltage just above the critical current $V(I_C)$ because it behaves like $|\cos 2\theta|$, which is expected for somewhat incoherent Cooper pair tunneling between d-wave superconductors (Klemm, 2005). Further insight into the pairing symmetry of the Cooper pairs in BSCCO is provided by the temperature dependence of Josephson coupling in the twisted junctions (Zhao et al., 2021; Martini et al., 2023; Lee et al., 2023). For $\theta \sim 0$, $I_C(T)R_N$ monotonically decreases as T increases, approximately following the theory curve for nearly incoherent tunneling between d-wave superconductors. However, a nonmonotonic behavior of $I_C(T)R_N$ appears when θ increases. For example, for $\theta = 29$ and 39 degrees, the $I_C(T)R_N$ increases alongside T , reaching a maximum value and then decreases as T approaches T_c (Zhao et al., 2021). For $\theta = (44.9 \pm 0.1)$ degrees junction, the $I_C R_N$ is about two orders of magnitude smaller than the 0 degree value. The origin of the finite supercurrent near 45 degrees is encoded in the Josephson current-phase relation (CPR) (Can et al., 2021; Sigrist, 1998; Goldobin et al., 2007). Using the Ginzburg–Landau theory on each layer it is possible to write the following CPR:

$$I(\phi) = I_{C1} \sin(\phi) - I_{C2} \sin(2\phi), \quad (1)$$

in which I_{C1} depends on the twisting angle θ according to the relation $I_{C1} \sim \cos(2\theta)$. The competition between the first and second terms in the previous equation underlies the emergence of the spontaneously broken time-reversal symmetry phase near the 45 degrees twist. In fact, When θ is close to zero, the conventional Josephson tunneling term I_{C1} dominates and the corresponding free energy minimum occurs at $\phi = 0$. However, $I_{C1} \sim \cos(2\theta)$ decreases when increasing the twist. Eventually, for a twist angle approaching 45 degrees, the I_{C2} term begins to dominate and the free energy develops two minima. This means that tunneling one by one of Cooper pairs across the junction is suppressed and a stronger link between the layers enables the transfer of multiple Cooper pairs in a single act of tunneling (Goldobin et al., 2007). The co-tunneling of Cooper pairs is predicted to support an interfacial SOP with emergent $d_{x^2-y^2} + id_{xy}$ symmetry (Sigrist, 1998; Yang et al., 2018; Can et al., 2021). The signature of the strong second-order harmonic $I_C \sim \sin(2\phi)$ can be experimentally probed by measuring the Fraunhofer pattern (Barone and Paterno, 1982) or microwave-induced Shapiro steps (Shapiro et al., 1964) in the I–V characteristic, which are both sensitive to the $4e$ charge of co-tunneling Cooper pairs across the junction (Sigrist, 1998; Yang et al., 2018; Goldobin et al., 2007).

Fraunhofer interference occurs when a JJ is subjected to an external magnetic field parallel to the junction plane. When θ approaches 45 degrees, the current-phase relation changes and the period of the Fraunhofer pattern becomes halved (Tummuru et al., 2022b). This period-halved contribution in the Fraunhofer pattern is rapidly lost when moving to θ under 40 degrees signaling the field dependence of the critical current can be tested to probe for spontaneous broken TRS.

Shapiro steps occur when the junction is continuously irradiated with microwaves at frequency f . The resonance between microwave and ac Josephson frequency resulted in quantized voltage steps, with a step height of $hf/2e$, in the I–V characteristic curve. When θ approaches 45 degrees, additional steps appear at fractional values $V_n/2$ because the second harmonic becomes dominant in the current-phase relation. Then the Shapiro steps are a manifestation of the tunneling of Cooper pairs across the barrier while the fractional steps, on the other hand, coincide with two Cooper pairs tunneling across the junction. In both cases whenever the potential energy across the junction is equal to the photon energy, or a multiple thereof, one or two Cooper pairs can absorb photons from the radiation field. Both the prediction for the Shapiro and the Fraunhofer have been confirmed in experiments (Zhao et al., 2021).

Although these experiments are hard to realize given the described fragility of these interfaces, the tantalizing perspective provided by the previous experimental fabrication advancements and observations encourages theory to propose novel architectures. Theoretically, the induced superconducting topological gap at the interface can be manipulated by controlling the 3D architecture of the material. Indeed, the twist degree of freedom of each layer can be tuned independently. Cuprate-twisted multilayers admit several inequivalent arrangements, which can improve the size of the topological superconducting gap and the superconducting region in the phase diagram (twist angle vs. temperature) where broken TRS broken states can be created and detected. As a function of the angle, two (three) Dirac cones merge to form a quadratic (cubic) band touching dispersion. This results in an alternated (chiral) twist symmetry, which can exhibit chiral topological superconductivity in an extended region of the twist-angle phase diagram (Tummuru et al., 2022a). In the chiral case, the angle of twisted trilayer cuprate heterostructures is predicted to exhibit a power-law divergent density of states. States that break TRS host chiral edge modes that always come in pairs and therefore do not require the inclusion of a zero-energy state, such as the Majorana fermions. However, we can create a topological phase with odd chiral edge modes by introducing a topological insulator with strong spin–orbit coupling as a substrate or as an encapsulation layer. The interface of a twisted cuprate bilayer can yield a topological phase with odd chiral edge modes (Margalit et al., 2022). The expected chiral mode can include a single chiral Majorana zero mode at each vortex if a perpendicular magnetic field is applied to the system (Mercado et al., 2022). Early work on interfacing topological insulators with (untwisted) Bi-2212 has already produced encouraging results (Zareapour et al., 2012). Although an additional study failed to detect a proximity-induced measurable gap (Xu et al., 2014), the research underscores the interest in twisted cuprate/topological insulators heterostructures fabrication.

Introducing twisted high-temperature superconductors in quantum circuits

As introduced before, the possibility to twist the BSCCO monolayers introduces a new degree of tunability which paves the way for superconducting technologies. JJ-based superconducting circuits are at the vanguard in many areas of microwave quantum circuits (Devoret and Schoelkopf, 2013; Devoret and Martinis, 2004) and they are used as state-of-the-art not only for qubits but also for readout amplifiers, cavities, detectors, circulators, and amplifiers (Bergeal et al., 2008; Frattini et al., 2018; Clarke and Braginski, 2006). In order to take advantage of these extraordinary properties explained previously, a promising pathway is to integrate the 2D twisted JJ composed of BSCCO flakes into conventional 3D superconducting circuits. Obviously, one of the most challenging parts is the creation of reliable superconducting contact between the 2D and 3D materials allowing the use of standard microwave readout and drive techniques. Once this aspect is overcome, there is the possibility of fabricating microwave resonant circuits allowing for high-quality hybrid circuits.

Microwave resonators are an indispensable element in the field of microwave quantum circuits. For example, they are the building blocks of superconducting photon detectors like SNSPD (Natarajan et al., 2012) or mKID (Day et al., 2003; Baselmans et al., 2008). In this sense, hybrid circuits incorporating a twisted BSCCO vdW heterostructure can be used as a novel inductive detector capable of detecting single photons in the low frequency (THz) regime, with micron spatial resolution given by the size of the flake. A photon hitting the superconductor generates quasiparticles above the gap, which are detected either via the resistive response (in SNSPDs) or via the reactive phase response (in mKIDs). Such a device can be used as a novel inductive detector capable of detecting single photons in the low frequency (THz) regime, with micron spatial resolution given by the size of the flake. Such a device is also useful for the basic study of superconductivity, as the superconducting circuit can probe the superfluid density of the BSCCO flake and explore its superconducting gap structure.

Furthermore, microwave superconducting resonators are widely used to build qubits. Since the first realization of the Cooper-pair box (Koch et al., 2007), superconducting qubit technology has evolved to become a leading modality for quantum computation (Bravyi et al., 2022). Employing other materials or devices with alternative electronic or degrees of freedom paves the way for novel and exotic qubits realizations. In this sense, integrating the resonator with the 2D BSCCO junction could be possible to create a platform toward qubits with unique properties and a new degree of tunability proper of this junction.

But hybrid superconducting circuits are interesting platforms not only for quantum computing technologies but also for fundamental sciences. The coupling between the superconducting resonator and the 2D BSCCO junction can be used to investigate, through a radio frequency measurement, the fundamental properties of the junction such as the CPR and the free energy. A hybrid device of such kind is a valuable tool to evaluate the contribution of the second harmonic in Eq. (1) for different twisting angles (Tummuru et al., 2022b). In particular, to perform this measurement, a superconducting resonator should be galvanically coupled with the junction, which is embedded in a SQUID loop as shown in the Fig. 5A.

Fig. 5 (A) Sketch of the proposed device able to measure the CPR of a junction. The twisted junction is embedded in a SQUID loop which is galvanically coupled to the resonator. (B1) Resonance deep produced by a 0 degree twist junction and (C1) the corresponding current phase relation. (B2) The same analysis has been done for θ near 45 degrees and (C2) additional shifts appear thanks to the dominance of the second harmonic contribution.

Applying a magnetic field in the superconducting loop, the phenomenon of flux quantization arises changing the Josephson inductance of the junction and consequently the resonance frequency of the device which is expressed as

$$f_{\text{res}} = \frac{1}{4I_{\text{res}} \sqrt{L_{\text{tot}} C_{\text{cpw}}}}, \quad (2)$$

where L_{tot} is the total inductance of the device containing the resonator inductance and the resulting inductance of the two junctions in the loop. Then, by probing the resonator in the radio frequency range, a direct measurement of the resonance shift for different twisting angles can be done. As shown in Fig. 5B1 and B2 additional shifts of the resonance frequency appear when the twisting angle approaches 45 degrees. From the behavior of the resonance frequency, by reconstructing the CPR, the second harmonic contribution in the JJ is evaluated as presented in Fig. 5C1 and C2. In this sense, the superconducting resonator could be a powerful tool to analyze the fundamental properties of the junction. Furthermore, it is important to underline that even though a lot of DC transport measurements have been performed on vdW heterostructures only in a few recent experiments, they have been integrated into cQED (Wang et al., 2019; Sinko et al., 2021). For this reason, this device could be the first important step toward the integration of vdW heterostructures in the field of quantum technologies.

Conclusion

By introducing new materials and experimental approaches, hybrid superconducting circuits can make a great contribution to quantum technologies and fundamental research. The unique electronic properties of these heterostructures make vdW BSCCO-based devices a promising alternative for constructing key elements of novel solid-state quantum computing platforms. Materials science is becoming an important element in the world of quantum circuits and soon may make significant contributions to the already thriving cQED sector. Given the promising results, in the near future, an integration of these novel materials in superconducting circuits is desirable in order to harness the properties of BSCCO heterostructures for use in the cQED architecture.

Acknowledgments

The experiment presented in Fig. 4 is the result of the work of Yejin Lee, Mickey Martini, Sanaz Shokri, Christian Saggau, and Tommaso Confolone. The crystals were provided by Genda Gu, Kenji Watanabe, and Takashi Taniguchi. Abstract

The novel opportunities offered by nanotechnologies and materials science have enlarged the physical conditions of occurrence of the Josephson effect. Semiconducting, ferromagnetic, topological-insulator, and graphene barriers lead to unconventional and anomalous aspects of the Josephson coupling, which might be useful to respond to some issues on key problems of solid-state physics. However, the complexity of the layout and the competing physical processes occurring in the junctions pose novel questions on the interpretation of their phenomenology. Measurements of critical current fluctuations have turned to be imaging tools of different dissipation processes, whose origin may depend on the type of the barrier, the nature of the interface, the geometry and dimensionality of the device. In this chapter, we classify some significant behaviors of unconventional junctions in terms of the temperature properties of the critical current fluctuations, thus providing accurate arguments to distinguish and understand physical processes occurring in quite different dynamical regimes. These notions are universal and apply to all kinds of junctions.

Key points

- Phase dynamics of a Josephson junction.
- Observation of macroscopic quantum phenomena through measurements of switching current distributions.
- Underdamped regime and moderately damped regime: the role of dissipation.
- Heating events in Josephson junctions characterized by high values of the critical current density.
- Capability to distinguish different dissipation sources in unconventional Josephson junctions: fingerprints of the switching current distributions.

Introduction

The possibility that a macroscopic system could behave quantum mechanically if it was suitably decoupled from its environment (Caldeira and Leggett, 1981; Clarke and Wilhelm, 2008; Devoret and Schoelkopf, 2013; Kockum and Nori, 2019) was somehow the start of an intense research activity aimed at investigating the boundary between the microscopic quantum and macroscopic classical worlds. Anthony J. Leggett immediately emphasized the importance of distinguishing macroscopic quantum phenomena originating in the superposition of a large number of microscopic variables (such as superfluidity and superconductivity) from those displayed by a single macroscopic degree of freedom (Caldeira and Leggett, 1981).

Because of their design scalability and their flexibility in controlling the level of damping, Josephson devices have proven to be a fantastic test bench for studying fundamental physics problems such as quantum coherence in macroscopic systems, taking advantage from the anharmonicity deriving from the Josephson equations (Josephson, 1962). In the 1980s, the macroscopic quantum tunneling (MQT), and therefore the macroscopic quantum nature of the phase difference φ across a Josephson junction (JJ), has been demonstrated (Voss and Webb, 1981; Jackel et al., 1981; der Boer and de Bruyn Ouboter, 1980; Prance et al., 1981; Dmitrenko et al., 1985; Washburn et al., 1985; Devoret et al., 1984, 1985; Clarke et al., 1988). These MQT experiments established that, although a JJ contains a large number of atomic constituents, it is atom-like in the sense that it has a macroscopic single degree of freedom behaving quantum mechanically (Clarke and Wilhelm, 2008; Devoret and Schoelkopf, 2013; Kockum and Nori, 2019). Thermal energy must be sufficiently low to avoid incoherent mixing of eigenstates, and the macroscopic degree of freedom must be sufficiently decoupled from other degrees of freedom for the lifetime of the quantum states to be long on the characteristic time scale of the system (Clarke et al., 1988).

Advances in materials science and in the application of nanotechnologies to superconducting devices are leading to novel and promising devices in view of quantum systems and superconducting quantum technologies (Koshino, 2023; Tafuri, 2023; Zaikin, 2023; Bergeret and Ilic, 2023), whose complete competitiveness has to be evaluated along with a possible impact on the fundamental themes of coherence and dissipation. Measurements of switching current distributions (SCDs) have turned to be

standard tools to investigate phase dynamics and dissipation phenomena in unconventional and hybrid systems and nanostructures (Massarotti and Tafuri, 2019). In the present Chapter, we look at phase dynamics aware that materials science is not only offering a variety of novel interfaces and junctions, but also radically new solutions of synthesizing hybrid Josephson devices taking advantage at the same time of the progress registered in using nanotechnologies in superconducting electronics and quantum circuits. In the following sections, the phenomenology of the switching current measurements will be addressed in most of the regimes interested by unconventional nano-devices and hybrid JJs.

Phase dynamics in the underdamped regime

A JJ consists of two superconducting electrodes separated by an insulating barrier of appropriate thickness, typically few nanometers, through which Cooper pairs can tunnel coherently. Josephson (1962) showed that the supercurrent I through the barrier is related to the gauge-invariant phase difference φ between the phases of the two superconductors by the current–phase relationship

$$I = I_{c0} \sin \varphi \quad (1)$$

where I_{c0} is the critical current of the junction in the absence of thermal fluctuations. In the presence of a potential difference V between the two electrodes, the phase difference evolves in time as

$$\frac{\partial \varphi}{\partial t} = \frac{2eV}{\hbar} \quad (2)$$

Eqs. (1) and (2) are the so-called Josephson equations. The more general case of barriers other than an insulating layer or with unconventional superconducting electrodes, such as high critical temperature superconductors (HTS), is discussed in Tafuri (2023).

In a quantum-mechanical picture, the two relevant operators are the phase difference φ , which is associated with the Josephson coupling energy $E_J = I_{c0}\hbar/2e$, and the Cooper-pair number difference N across the junction capacitance C , which is associated to the charging energy $E_c = e^2/2C$. Therefore, in the absence of dissipation, the behavior of a JJ can be described by an Hamiltonian $\mathcal{H}$, which is a function of the phase difference φ and of the charge Q transferred between the electrodes (Iansiti et al., 1987; Tinkham, 1996; Kockum and Nori, 2019):

$$\mathcal{H}(\varphi, Q) = E_c(Q/e)^2 - E_J \cos \varphi \quad (3)$$

As in the case of position and momentum operators x and p_x , the operators for φ and for the charge on the capacitor Q are canonically conjugate. The fact that φ and Q are subject to Heisenberg's uncertainty principle has important consequences. When $E_J \gg E_c$, φ is well defined and Q has large quantum fluctuations; therefore, the Josephson nature of the junction dominates. On the other hand, when $E_J \ll E_c$, N is well defined and φ has large quantum fluctuations; therefore, the charging nature of the capacitor is dominating. More details can be found in Chapter (Tafuri, 2023).

In this chapter we will consider the more standard condition $E_J \gg E_c$ and dissipation arising from the environment will be discussed. If the condition $E_J \gg E_c$ is satisfied, the charging energy in Eq. (3) can be disregarded. Therefore, the phase difference φ is well defined and governs the dynamics of a current-biased JJ. In the framework of the Resistively and Capacitively Shunted Junction (RCSJ) model (Barone and Paternò, 1982; Likharev, 1979), according to which a real junction is modeled as an ideal JJ in parallel to the junction capacitance C , which arises from the dielectric nature of the barrier, and a dissipative resistor R (inset of Fig. 1A), the phase dynamics is equivalent to the motion of a particle in a washboard potential $U = -E_J(\cos \varphi + \varphi I/I_{c0})$ (see Fig. 1A):

$$\left(\frac{\Phi_0}{2\pi}\right)^2 C \frac{\partial^2 \phi}{\partial t^2} + \left(\frac{\Phi_0}{2\pi}\right)^2 \frac{1}{R} \frac{\partial \phi}{\partial t} + \frac{\partial}{\partial \phi} U = 0, \quad (4)$$

where $\Phi_0 = h/2e$ is the flux quantum and the tilt of the washboard potential is given by the bias current I . The term involving the capacitance C represents the mass of the particle and the $1/R$ term represents the damping of the motion. For $I < I_{c0}$, the potential U has local minima where the phase particle is trapped and oscillates at the plasma frequency $\omega_p = \omega_0(1 - i^2)^{1/4} = \sqrt{2eI_{c0}/\hbar C}(1 - i^2)^{1/4}$, where $i = I/I_{c0}$. The strength of the friction can be expressed through the junction quality factor $Q = \omega_p RC$, which depends on the junction capacitance C , on the dissipative element R and on the critical current, which in turn is proportional to the Josephson coupling energy E_J . According to the mechanical analogy provided by the RCSJ model, low damping corresponds to $Q \gg 1$, while the junction is overdamped for $Q < 1$. When ramping the bias current I , the tilt of the energy potential increases and the height $\Delta U(i) = 4\sqrt{2}/3 \cdot E_J(1 - i)^{3/2}$ of the energy barrier between consecutive wells decreases. In absence of thermal fluctuations, for $I = I_{c0}$ the phase will escape from the well and roll down the washboard potential. Therefore a voltage will appear at the junction's edges. Decreasing the bias current, the potential tilt will be reduced and for $I = I_R$, the particle will be retrapped in a well, returning to the zero voltage state. Therefore I_R is known as the retrapping current. In the case of underdamped junctions, hysteresis is present in the current–voltage (I – V) characteristic and the voltage will switch abruptly from the zero voltage state to about twice the superconducting gap Δ/e (see Fig. 1B).

Fig. 1 (A) Phase dynamics of an underdamped current biased JJ. The equivalent RCSJ circuit is shown as the inset of panel (A). In the superconducting state (zero voltage state) the phase particle is confined to one well of the washboard potential where it oscillates back and forth and the average voltage is zero. The phase particle can escape from the well either by thermal activation (TA) (blue arrow) or macroscopic quantum tunnelling (MQT) (red dashed arrow) and the system switches to the running state (orange dashed arrow). (B) The escape is a stochastic phenomenon; thus the distribution of the switching events can be measured by repeatedly sweeping the bias current (orange points superimposed on a typical I - V characteristic of an underdamped JJ). (C) Measurements of SCDs as a function of the temperature: by increasing T the histograms move to lower currents and their standard deviation σ increases, according to the TA regime. The temperature dependence of σ (blue up triangles) and of the mean switching current I_M (red points) are both reported in panel (D): below the crossover temperature T_{cross} the histograms overlap and both I_M and σ saturate.

Due to the effects of thermal fluctuations and quantum tunneling, the junction may switch to the finite voltage state for values of $I < I_{c0}$. The bias current at which the transition to the finite voltage state occurs is the switching current I_{sw} , depicted in Fig. 1B along with a typical SCD. Such a transition corresponds to the particle escaping from the well either by a thermally activated process (Kramers, 1940) (blue arrow in Fig. 1A) or by tunneling through the barrier potential, the MQT process (red dashed arrow in Fig. 1A) or the quantum decay of the macroscopic phase difference φ from a metastable state (Caldeira and Leggett, 1981). The relative weight of these two escape processes depends on the temperature of the system and on the junction plasma frequency. For $k_B T \gg \hbar \omega_p$, the escape process is dominated by TA with a rate given by the Arrhenius law (Kramers, 1940):

$$\Gamma_T(i) = a_T \frac{\omega_p}{2\pi} \exp\left(-\frac{\Delta U(i)}{k_B T}\right), \quad (5)$$

where $a_T = 4/[(1+Qk_B T/1.8\Delta U)^{1/2}+1]^2$. The escape rate will be dominated by MQT at low enough temperature (Caldeira and Leggett, 1981): for i close to one and to the lowest order in $1/Q$, it is approximated by

$$\Gamma_q(i) = a_q \frac{\omega_p}{2\pi} \exp\left[-7.2 \frac{\Delta U(i)}{\hbar \omega_p} \left(1 + \frac{0.87}{Q}\right)\right], \quad (6)$$

where $a_q = (864\pi\Delta U/\hbar\omega_p)^{1/2}$. The MQT rate is affected by dissipation, the irreversible energy transfer between the system and the environment, described by the junction quality factor Q (Caldeira and Leggett, 1981).

The crossover temperature T_{cross} between the thermal and quantum regimes is given by (Grabert et al., 1987)

$$T_{cross} = (\hbar\omega_p/2\pi k_B) \left[(1 + 1/4Q^2)^{1/2} - 1/2Q \right] \quad (7)$$

The behavior of the phase difference φ is deduced from measurements of the escape rate Γ from the zero-voltage state. To determine the escape rate, 10^4 – 10^5 switching events are typically collected at fixed temperature. In order to investigate the phase dynamics of Josephson devices, the bias current of the junction is ramped at a constant sweep rate, the voltage is measured using a low noise differential amplifier and is usually fed into a threshold detector which is set to generate a pulse signal when the junction switches from the superconducting state to the finite voltage state. This signal is used to trigger a fast voltmeter to record the value of the bias current I_{sw} at which the transition to the running state occurs (Massarotti and Tafuri, 2019). The resulting distribution of the

switching probability $P(I)$ is used to compute the escape rate out of the zero-voltage state as a function of the bias current I (Fulton and Dunkleberger, 1974):

$$\Gamma(I) = \frac{1}{\Delta I} \frac{dI}{dt} \ln \left(\frac{\sum_{i \geq I} P(I)}{\sum_{i \geq I + \Delta I} P(I)} \right) \quad (8)$$

where dI/dt is the current ramp rate and ΔI is the channel width of the analog-to-digital converter.

The first experiments on the transition from the thermal to the quantum regime in a JJ were carried out by Voss and Webb (1981) and by Jackel et al. (1981), while related experiments on a junction inserted in a superconducting loop were realized by der Boer and de Bruyn Ouboter (1980), Prance et al. (1981), and Dmitrenko et al. (1985). The temperature dependence and the effect of damping on the tunneling have been addressed by later experiments (Washburn et al., 1985). Devoret et al. (1985) have established a detailed conceptual and experimental protocol to follow to prove the macroscopic quantum nature of the phase difference across a JJ and the crossover to the thermal regime, used in most of later experiments. The problem of the impedance presented to the junction at microwave frequencies by the wires directly connected to it has been clearly addressed, and classical phenomena have been used to measure all relevant parameters of the junction in situ (Devoret et al., 1984, 1985). In particular, the magnetic field has been used as a knob to tune the crossover temperature by changing the critical current and therefore the plasma frequency. This represents a crucial test to distinguish macroscopic quantum phenomena from classical effects related to heating or spurious noise in the measurement setup (Devoret et al., 1985; Clarke et al., 1988).

In underdamped JJs, the typical behavior of the SCDs is reported in Fig. 1C and presents a characteristic temperature behavior: by reducing the temperature T the mean value of the switching histogram I_M moves to higher currents and their standard deviation σ scales with the temperature down to T_{cross} which is defined as the temperature below which the histograms overlap and do not depend any more on the temperature. For $T < T_{\text{cross}}$ both the mean value I_M and the standard deviation σ of the switching histograms saturate, indicating the transition to the MQT regime, as schematically shown in Fig. 1D.

Moderately damped regime

In underdamped junctions, a single escape event is enough for the junction to switch to the running state. This occurs since the kinetic energy gained by the phase particle running down in the tilted washboard potential is not all dissipated, but enough energy remains to carry the phase over the next well. In the case of moderately damped regime (MDR) ($1 < Q < 5$), following an event of escape, the particle may travel down the potential for few wells and then is retrapped in one of the following minima of the potential, as shown by the green dashed arrow in Fig. 2A. At low bias the process of escape and retrapping occurs multiple times, thus

Fig. 2 (A) The equivalent circuit in the framework of frequency dependent RCSJ model is shown as the inset. Due to onset of multiple escape (TA or MQT, blue and red dashed arrows, respectively) and retrapping processes (green dashed arrow), at low bias the phase particle diffuses along the tilted washboard potential, until an increase of the tilt raises the velocity and the phase particle can switch to the running state. (B) I - V characteristics display both hysteresis and a PD branch (signaled by the green dashed line) at small voltages. (C) SCD histograms are schematized as a function of the temperature in the moderately damping regime, with a clear nonmonotonic behavior when increasing T . (D) Temperature dependence of σ . Its behavior is qualitatively quite different when compared to the underdamped case, providing distinct signatures of the phase dynamics.

inducing a diffusive motion of the phase particle until an increase of the tilt of the potential, due to a change in the bias current, raises the velocity of the particle and the transition to the running state occurs.

If the Josephson energy E_J is of the order of the thermal energy $k_B T$, the competition between multiple escape and retrapping processes prevents the access to the running state and leads to the appearance of a non zero voltage, manifesting as a phase diffusion (PD) branch in the I - V characteristic (Barone and Paternò, 1982; Iansiti et al., 1987; Kautz and Martinis, 1990; Vion et al., 1996), as schematically reported in Fig. 2B. The analytical expression for the retrapping rate from the resistive to the superconducting state is given by (Stewart, 1968; Ben-Jacob et al., 1982)

$$\Gamma_R(I) = \omega_p \frac{I - I_{R0}}{I_{c0}} \sqrt{\frac{E_J}{2\pi k_B T}} \exp \left[\frac{-E_J Q^2 \left(\frac{I - I_{R0}}{I_{c0}} \right)^2}{2k_B T} \right], \quad (9)$$

where I_{R0} is the fluctuation-free retrapping current. Kautz and Martinis (1990), following the works by Ono et al. (1987), have shown both experimentally and theoretically that hysteresis and PD can coexist, within the RCSJ model, if frequency-dependent damping is taken into account. In a typical experimental setup, the junction is also capacitively (C_s) and resistively (R_s) shunted by the leads attached to the junction itself. A more realistic equivalent circuit of the junction is reported in the inset of Fig. 2A rather than the simple RCSJ model of Fig. 1A.

At low frequencies, the dissipation is mostly determined by the junction resistance R , but at high frequencies (usually ω_p is of the order of 10 GHz) the impedance is typically small because C_s acts as a short and R_s is small compared to R . In the zero voltage state, the phase oscillates in a well at the plasma frequency and it may transit from one well to another in a time which is of the order of the inverse of the plasma frequency. In this case, dissipation is thus characterized by $R(\omega \approx \omega_p)$. Without a specially designed environmental circuit, this high frequency dissipation is usually of the order of the impedance of the leads ($\approx 100 \Omega$). After the switching to the running state, dissipation takes place at low frequencies ($\omega \approx 0$) so that junctions are overdamped at high frequencies but are in the underdamped limit at low frequencies (Kautz and Martinis, 1990; Vion et al., 1996; Massarotti and Tafuri, 2019).

PD phenomena are typical of the MDR, characterized by values of Q ranging from 1 to 5. It represents the technological result of the application of nanotechnology to more standard Josephson devices based on conventional low temperature superconductors (LTS) (Kautz and Martinis, 1990; Männik et al., 2005; Kivioja et al., 2005; Krasnov et al., 2005; Massarotti and Tafuri, 2019), and of the implementation of novel types of hybrid systems. For LTS systems, once the barrier thickness and the critical current density I_c have been fixed, a reduction in its size unavoidably leads to a lowering of the critical current and determines a quite different phase dynamics (Iansiti et al., 1987; Kautz and Martinis, 1990; Vion et al., 1996; Männik et al., 2005; Kivioja et al., 2005; Yu et al., 2011). Lower critical currents result in lower Josephson energies, and higher levels of dissipation are expected. The same regime can be controllably induced in larger junctions in case of low I_c (Longobardi et al., 2011a, b; Massarotti et al., 2012), or with lower reproducibility in junctions with larger intrinsic dissipation levels, as occurring in HTS systems (Krasnov et al., 2005; Bauch et al., 2005, 2006; Inomata et al., 2005; Bae et al., 2009). The low I_c limit seems to be characteristic also of all futuristic nano-hybrid devices incorporating nanowires, and the MDR is intrinsically more common than it could be expected (Zhang et al., 2008; Borzenets et al., 2011).

In the MDR, I_c usually ranges from a few hundred nA to a few μA , thus satisfying the condition $E_J \gg k_B T$. The I - V characteristics are hysteretic and the transition to the running state is a stochastic phenomenon. In addition to the usual crossover between MQT and TA behavior, measurements of SCDs (reference temperature behavior is reported in Fig. 2C) have shown the transition from TA to the PD regime, indicated by a characteristic dependence of σ , as the appearance of an anticorrelation between the temperature and the width of the switching distributions (Männik et al., 2005; Kivioja et al., 2005; Krasnov et al., 2005; Bae et al., 2009; Longobardi et al., 2011a, b; Massarotti et al., 2012). After the MQT saturation at the lowest temperatures, σ follows the expected $T^{2/3}$ dependence, deviations are evident in proximity and above a transition temperature T^* that is defined as the temperature at which the width σ of the SCD reaches the maximum value, as shown in Fig. 2D. A decrease of the Josephson energy E_J and of the quality factor Q enhances the retrapping probability Γ_R , as shown by Eq. (9), causing multiple retrapping phenomena in the switching dynamics. Above T^* histograms shrink rather than broaden with a consequent increase of their maximum (see Fig. 2C). The decreasing behavior of σ when increasing the temperature and a modification of the shape of the distributions at around T^* turn to be distinctive signatures of the PD regime. Such an anomalous behavior can be explained by considering the competition between thermal escape and multiple retrapping processes in the switching dynamics (Fenton and Warburton, 2008; Zonda et al., 2015). For $T < T^*$, thermal escape dominates on the retrapping rate, differently from the case $T > T^*$.

The symmetrization of the switching distribution due to the interplay between escape and retrapping events can be clearly measured by considering the skewness of the distributions γ as a function of the temperature. γ is the ratio m_3/σ^3 where m_3 is the third central moment of the distribution. In the MQT and TA regimes, where retrapping processes are negligible, $\gamma = -1$, which is consistent with a typical escape rate which follows the Arrhenius law (Massarotti and Tafuri, 2019; Longobardi et al., 2011a; Fenton and Warburton, 2008; Murphy et al., 2013). As the temperature increases and the junction falls in the PD regime, the distributions become more and more symmetric as γ tends to zero. Therefore, the switching events on the left side of the distribution (ascending side), which occur for lower values of the bias current, are prevented by phase retrapping, with a consequent symmetrization of the SCDs (Massarotti and Tafuri, 2019; Longobardi et al., 2011a; Fenton and Warburton, 2008; Murphy et al., 2013).

The possibility to have extremely low I_c can be functional to investigate phase dynamics at extreme conditions. In recent experiments on submicron Nb/AlOx/Nb junctions (Yu et al., 2011) an anomalous $\sigma(T)$ dependence with a negative $d\sigma/dT$ over the

entire temperature range has been observed. This regime can be achieved by engineering junctions with lower critical current and junction capacitance such that the ratio I_{c0}/C , which regulates T_{cross} , is constant and the transition temperature T^* , which scales with the Josephson energy (Krasnov et al., 2005), is lower or comparable to the quantum crossover temperature T_{cross} . Another example is given by the work by Yoon et al. (2011). They have engineered Al/AlOx/Al JJs in order to obtain low critical currents, of about 400 nA, and low capacitance, of about 40 fF, at the same time. In this way they have observed that TA is completely suppressed since T^* is lower than T_{cross} . On the other hand, TA regime is recovered by adding a shunting capacitance in the device circuit, and this demonstrates that the capacitance can be used in order to tune the phase dynamics.

Similar phenomenology of the SCDs, as reported in Fig. 3A and B, can be achieved by using unconventional HTS Josephson devices, such as YBCO grain boundary (GB) biepitaxial JJs (Bauch et al., 2005, 2006; Stornaiuolo et al., 2013). In particular, it is possible to engineer devices with $T^* < T_{cross}$ (Longobardi et al., 2012), to which correspond a direct transition from MQT to the PD regime, and TA is completely suppressed. For temperatures well below T_{cross} , MQT contributions to escape rates are larger than those coming from both thermal escape and retrapping processes (see Fig. 3C), while above T_{cross} the retrapping rate dominates over thermal and quantum escape rates (see Fig. 3D).

The typical temperature behavior of σ in this regime is shown in Fig. 3A. Below T_{cross} , histograms overlap and σ saturates, which is a typical signature of a quantum activation regime. In analogy to what commonly done to prove MQT in underdamped junctions (Devoret et al., 1985; Clarke et al., 1988; Massarotti and Tafuri, 2019), the magnetic field can be used to tune in situ T_{cross} to unambiguously prove MQT as source of the saturation of σ . In the presence of magnetic field, a lower value of T_{cross} and lower values of σ are observed, as schematically sketched in Fig. 3C and expected from the theory (see Eq. 7). In Fig. 3A, increasing the temperature above T_{cross} , the switching current histograms shrink rather than broaden, which corresponds to the negative temperature derivative of σ in Fig. 3B. This behavior is consistent with a diffusive motion due to multiple escape and retrapping processes in the potential wells.

The experimental results and the numerical outcomes can be condensed in a phase diagram, which includes the various activation regimes (Kivioja et al., 2005; Longobardi et al., 2012). The phase diagram is a function of the characteristic scaling energies E_J and $k_B T$ and of the dissipation parameter Q ; therefore it is valid in a large range of dissipation conditions and constitutes a functional guide to classify the switching behavior of a JJ. Moreover, it is a reference for phase dynamics of novel types of junctions and systems for which the nature of the current-induced transition from the superconducting to the normal state has not been completely clarified.

The very high critical current density regime

The temperature behaviors of critical current fluctuations reported in the previous sections are typical of JJs characterized by critical current density J_c in the range $10\text{--}10^3\text{ A/cm}^2$. Recently, measurements of SCD have been performed on a series of different nanostructures (Murphy et al., 2013; Li et al., 2011; Sahu et al., 2009; Murphy et al., 2015; Massarotti et al., 2015b; Baumans et al., 2017; Ejrnaes et al., 2019; Salvoni et al., 2022; Zgirski et al., 2020, 2021; Zhang et al., 2022). Some of them are junctions and they can be classified in the schemes described in the previous sections. Some of them are simple nanowires (Zaikin, 2023). A subtle path exists between these different systems with analogies and distinctive features. When considering that a micro-bridge of width of the order of the coherence length behaves as a JJ (Barone and Paternò, 1982; Likharev, 1979), measurements of SCDs will turn to be a direct

Fig. 3 (A) SCDs as a function of T when the PD transition temperature T^* is lower than the quantum crossover T_{cross} and TA is suppressed. (B) Temperature behavior of σ for $H=0$ (black points) and in the presence of magnetic field (red triangles): the magnetic field reduces both T_{cross} and the values of σ , thus confirming that spurious noise can be disregarded as the origin of σ saturation. Schematic escape rates of MQT, TA, and retrapping processes at $T < T_{cross}$ (panel C), MQT escape rate dominates) and at $T > T_{cross}$ (panel D, retrapping processes dominate).

way of discriminating the phase dynamics and the transport in nontrivial cases, which are going to be more and more common with advances in nano-patterning superconductors at extreme scales.

Recent experiments on superconducting nanowires have shown an anticorrelation between the bath temperature and the width of the switching distributions (Li et al., 2011; Sahu et al., 2009; Murphy et al., 2015; Baumans et al., 2017; Ejrnaes et al., 2019; Salvoni et al., 2022). A numerical model in order to study the stochastic aspects of the switching dynamics in these devices has been developed by Shah et al. (2008). The model is based on a freestanding wire of effective length L and cross-sectional area A , the ends of which are at the bath temperature T_b . All heat generated locally in the wire can be taken away only through the ends. The stochasticity inherent in the switching process is based on the fact that the resistive fluctuations of the superconducting nanowire consist of discrete phase-slip events that occur at random instants and are centered at random spatial locations along the wire (Little, 1967; Zaikin, 2023). Given that edge effects favor phase-slip locations away from the wire ends, the source term is restricted to the region at the center of the wire of length W (Shah et al., 2008). Stochastic phase slips that heat the wire and heat dissipation that cools the wire are the dominating mechanisms. Since the phase-slip rate depends on the local temperature of the wire, heating by phase slips can create a runaway cascade that eventually overheats the wire. More details can be found in Massarotti and Tafuri (2019).

The stochastic phase-slip dynamics is reduced to the following ordinary differential equation for the time evolution of the temperature of the central segment (Shah et al., 2008):

$$\frac{dT}{dt} = -\alpha(T, T_b)(T - T_b) + \eta(I, T) \sum_i \delta(t - t_i) \quad (10)$$

The relaxation coefficient $\alpha(T, T_b)$ depends on the thermal conductivity $K(T)$, on the thermal capacity $C_v(T)$ of the phase slip volume, and on T_b (Shah et al., 2008). The second term on the right-hand side corresponds to stochastic heating by phase slips, whose rate $\Gamma(I, T)$ is temperature and current dependent and follows the Arrhenius law:

$$\Gamma(I, T) = \Omega(I, T) \exp - \frac{\Delta F(I, T)}{k_B T} \quad (11)$$

where $\Omega(I, T)$ is the attempt frequency (Shah et al., 2008; Massarotti et al., 2015b) and $\Delta F(I, T)$ is the free energy barrier given by (Little, 1967):

$$\Delta F(I, T) = \left[\frac{\sqrt{6}\phi_0 I_c(T)}{k_B T} (1 - I/I_{c0})^{5/4} \right], \quad (12)$$

If T_i and T_f are the temperatures before and after a phase slip, respectively, the temperature jump $\eta(I, T)$ due to a phase slip can be expressed as

$$A \cdot W \int_{T_i}^{T_f=T_i+\eta} C_v(y) dy = hI/2e. \quad (13)$$

The first term in Eq. (10) represents the cooling mechanism as a result of conduction of heat from the central segment to the external bath via the two end segments, each of length $(L - W)$. The temperature-dependent cooling rate is given by

$$\alpha(T, T_b) = \frac{4}{W(L - W)C_v(T)} \frac{1}{T - T_b} \int_{T_b}^T dy K(y) \quad (14)$$

In addition to restrictions on length scales, in the equations above the time for a phase slip and the quasiparticle thermalization time are both assumed to be smaller than the heat diffusion time (Shah et al., 2008).

Solutions of Eq. (10) have been performed numerically by Shah et al. (2008) in a wide range of temperature and current. At low temperatures the occurrence of just one phase-slip is sufficient to cause the nanowire to switch from the superconducting to the resistive state. In this temperature range, the width of the switching histograms increases when increasing the temperature, following the usual TA expressed by the Arrhenius law.

Such a broadening in the distribution width is indeed obtained up to a crossover temperature. At higher temperatures, the distribution width shows an anomalous decrease since histograms begin to shrink rather than broaden. Therefore, one phase slip is not sufficient to induce switching and multiple phase slips are needed. Such striking behavior of the distribution width may be understood by the following argument: the larger the number of phase slips in the sequence inducing the transition from the superconducting to the resistive state, the smaller the stochasticity in the switching process and, hence, the sharper the distribution of switching currents (Shah et al., 2008; Sahu et al., 2009; Murphy et al., 2015; Baumans et al., 2017; Ejrnaes et al., 2019). As in the case of moderately damped JJs, the change in the sign of the derivative of $\sigma(T)$ is related to a change in the phase-slips dynamics from single to multiple phase-slips fluctuations in the wire.

Typical measurements of SCDs on high J_c JJ are reported in Fig. 4A (Massarotti et al., 2015b). In this case, the critical current of the junction is about 50 μ A and the junction width is about 200 nm; thus the resulting J_c is of the order 10^5 A/cm², from one to two orders of magnitude larger than the junctions analyzed in the previous sections, thus J_c high values close to those observed in nanowires (Li et al., 2011; Sahu et al., 2009; Murphy et al., 2015). For high values of J_c , the phase dynamics is radically different

Fig. 4 (A) SCDs measured on high J_c JJ in a wide range of temperatures. (B) Temperature dependence of σ of high J_c JJ (black circles) is compared to those calculated through numerical simulations within the RCSJ model based on different values of Q (the lines are a guide for the eye). The transition temperature T^* and the shape of $\sigma(T)$ in the PD regime are both affected by the junction quality factor Q , while the temperature behavior of σ of high J_c JJ cannot be reproduced within the RCSJ model.

above the transition temperature, defined as the maximum of $\sigma(T)$. In particular, the rate of decrease of $\sigma(T)$ above its maximum value turns to be a distinctive marker of the phase dynamics. In the high J_c JJ, the slope of $\sigma(T)$ is much smaller when compared to those of moderately damped JJs, as shown in Fig. 4B where the temperature behavior of σ is reported as a result of numerical simulations for different values of the Q factor. The smooth decrease of $\sigma(T)$ cannot be described in terms of the intermediate dissipation regime: according to the RCSJ model, keeping all the other junction parameters fixed, an increase of J_c leads to an enhancement of I_c and Q . The increase of Q moves T^* to higher values, and the negative slope of $\sigma(T)$ above T^* becomes steeper and steeper, as shown by the numerical simulations for Q ranging between 1 and 5 reported in Fig. 4B.

The switching dynamics of JJs in the J_c interval 10^4 – 10^5 A/cm² can be consistently reproduced by considering a transition driven by local heating events, as shown in Massarotti et al. (2015b) and Baumans et al. (2017) possibly induced by intrinsic inhomogeneous composition unavoidable for high J_c junctions. Large values of Joule power density deposited in the weak link can induce a self-heating process during the switch to the resistive branch (Courtois et al., 2008). The absence of a set of self-consistent electrodynamics parameters to describe the temperature behavior of the SCDs is a strong indication of the failure of the standard Josephson dynamics. For larger values of J_c , heating driven mechanisms become dominant with a transition to the normal state locally in the junction area. These events can be modeled as heating events, as confirmed by the details of the simulations which are reported by Massarotti et al. (2015b), Baumans et al. (2017), and Shah et al. (2008), in the sense that they are local processes, break the coherence of the phase information, and are described by a heat diffusion-like equation.

As it occurs in superconducting nanowires, the temperature jump $\eta(T)$ depends on temperature because the specific heat is strongly temperature-dependent. At low temperatures, the specific heat is quite low; thus with each heating event there is a considerable increase in the temperature. In addition, the thermal conductivity and the thermal capacity are both quite low as the system is deeply into the superconducting phase. The junction is rather isolated from the environment and the heating event is destructive for the superconducting state. For this reason a single heating event can induce a direct jump to the resistive state at low temperatures: it induces a large local heating that is difficult to dissipate (Massarotti and Tafuri, 2019; Massarotti et al., 2015b). At high temperatures, the temperature jump $\eta(T)$ per heating event is rather small. In addition both the thermal conductivity and the thermal capacity increase with increasing temperature as well. Thermal diffusion and contact with the environment is more effective and multiple heating events are required for switching. This occurs at higher temperatures, where the derivative $d\sigma/dT$ is negative.

Therefore, it turns out that SCDs allow to distinguish different dissipation processes: a JJ cannot sustain an unlimited increase in the critical current I_c , and thus in the quality factor Q , through larger critical current density J_c while still preserving all the properties of the Josephson effect and all the features of the underdamped regime (Massarotti and Tafuri, 2019). The classical Josephson phase dynamics, which takes place in junctions characterized by lower critical current densities J_c , is replaced at high J_c values by a regime driven by local heating events where phase information is lost. Nonequilibrium phenomena produce hysteretic I - V characteristics and modify the influence of dissipation, thus becoming measurable through modeling of the SCDs in terms of heating modes (Shah et al., 2008; Massarotti et al., 2015a, b).

Conclusion

Every experiment or application using a superconducting weak link is based on how the phase difference φ between the electrodes evolves in time and space. The large variety of barriers now available between the superconducting electrodes offer novel functionalities and efficient tuning of physical processes occurring at the nanoscale and at different interfaces. Measurements of SCDs focus on the moment at which resistance originates in superconducting weak links; thus they constitute a direct way of discriminating the phase dynamics and the transport also in nontrivial cases of Josephson nanodevices and hybrid systems (Feofanov et al., 2010; Inomata et al., 2005; Massarotti et al., 2015a; Goldobin et al., 2007; Sickinger et al., 2012; Goldobin et al., 2013; Ahmad et al., 2020). These junctions are going to be more and more common with advances in nanopatterning superconductors and in materials science; thus the range of the energy dynamical parameters is significantly enlarged. In this chapter

we have represented well-defined criteria to identify different regimes of the phase dynamics. We believe that further progress in the field will lead to novel insights and a wide vision on macroscopic quantum phenomena in a variety of complementary systems, thus promoting novel arguments on the interplay of coherence and dissipation in solid state systems. Issues on a more detailed understanding of coherence, dissipation, and noise in the various devices play a significant role in the progress of quantum circuits (Larsen et al., 2015; de Lange et al., 2015; Wiedenmann et al., 2016; Ahmad et al., 2022).

Abstract

The last decade has been marked by great interest in the dynamics of vortices moving at high (>10 km/s) velocities in superconductors. However, the flux-flow instability (FFI) prevents its exploration and sets practical limits for the use of vortices in various applications. Even so, FFI has turned into a valuable tool for studying the quasiparticle energy relaxation in superconductors, with the view of enhancement of the single-photon detection capability of micrometer-wide strips operated at large bias currents. In this context, the failure of “global” FFI models for materials with strong intrinsic and edge vortex pinning has urged the elaboration of “local” FFI models. This chapter outlines the recent advances in the research on FFI and highlights superconductors with perfect edges and weak volume pinning as prospective materials for studying fast vortex dynamics and nonequilibrium superconductivity.

Key points

- Flux-flow instability at high vortex velocities.
- Pinning effects on the flux-flow instability.
- Paradigm shift from global to local instability models.
- Fast vortex motion at a microwave ac stimulus.

Introduction

Fast vortex dynamics and related nonequilibrium phenomena are essential subjects of research in modern superconductivity (Bezuglyj et al., 2019; Budinska et al., 2022; Buh et al., 2015; Cherpak et al., 2014; Dobrovolskiy et al., 2020a; Dobrovolskiy et al., 2019a; Dobrovolskiy et al., 2020c; Embon et al., 2017; Grimaldi et al., 2015; Gurevich, 2014; Kogan and Nakagawa, 2021; Kogan and Nakagawa, 2022; Kogan and Prozorov, 2020; Lara et al., 2017; Lyatti et al., 2020; Madan et al., 2018; Pathirana and Gurevich, 2021; Puica et al., 2012; Sheikhzada and Gurevich, 2017; Sheikhzada and Gurevich, 2020; Wördenweber et al., 2012). High velocities of magnetic flux quanta (Abrikosov vortices or fluxons) attract great interest because of the fundamental questions regarding their stability as topological excitations of the superconducting order parameter ψ and the ultimate speed limits for magnetic flux transport via vortices at intense transport currents. Furthermore, fast dynamics of fluxons determines the vortex-assisted mechanism of the initial dissipation of superconducting microstrip single-photon detectors (Korneeva et al., 2020; Vodolazov, 2017) and makes accessible novel phenomena in hybrid superconductor-based systems, such as the generation of sound (Bulaevskii and Chudnovsky, 2005; Ivlev et al., 1999) and spin (Bespalov et al., 2014; Dobrovolskiy et al., 2021) waves, as well as emerging functionalities, e.g., in microwave radiation/detection (Bulaevskii and Chudnovsky, 2006; Dobrovolskiy et al., 2018; Dobrovolskiy et al., 2020b; Löscher et al., 2019).

Probing the upper speed limits for vortices represents a valuable approach for studying the energy relaxation processes in superconductors (Attanasio and Cirillo, 2012; Knight and Kunchur, 2006; Leo et al., 2011; Leo et al., 2020a). This method allows one to quantify the lifetimes of quasiparticles (unpaired electrons) when their energy distribution is out of equilibrium. The physical phenomenon underlying this approach is termed *flux-flow instability* (FFI) (Bezuglyj and Shklovskij, 1992; Kunchur, 2002; Larkin and Ovchinnikov, 1975; Larkin and Ovchinnikov, 1986). In the current-voltage (I - V) curve of superconductors, FFI becomes apparent as a discontinuous jump to a highly resistive state at some instability current I^* which corresponds to the instability voltage V^* , see Fig. 1A. Note that I^* is usually smaller than the maximal current a superconductor can carry without dissipation—the *depairing current* I_d , thereby setting the actual limit for the use of superconductors in applications. The instability

Fig. 1 (A) Typical I - V curve of a superconductor in the mixed state, with the indicated instability current I^* and instability voltage V^* , and the regimes of pinned vortices (I), depinning transition (II), flux flow (III), nonlinear conductivity (IV), flux-flow instability (V), and highly-resistive state (VI). (B) Predictions of different FFI models for v^* vs B . LO: (Larkin and Ovchinnikov, 1975), BS: (Bezuglyj and Shklovskij, 1992), D: (Doettinger et al., 1995), K: (Kunchur et al., 2001), G: (Grimaldi et al., 2010), S: (Shklovskij, 2017), V: (Vodolazov, 2019). (C) Different FFI regimes on the B - T plane. B_t : overheating field in the BS model (Bezuglyj and Shklovskij, 1992). (D) Temperature dependences of the inelastic electron-electron and electron-photon scattering rates. T_x : crossover temperature.

voltage allows one to quantify the maximal vortex velocity (instability velocity) v^* by using the standard relation $v^* = V^*/(BL)$, where B is the magnitude of the applied magnetic field and L the distance between the voltage leads. The understanding of the microscopic mechanisms determining the maximal vortex velocities and the behavior of $v^*(B)$ is an essential task in the FFI research, see Fig. 1B.

Reviews and discussions of FFI and nonlinear effects occurring during fast vortex motion are given in Attanasio and Cirillo (2012), Dean and Kunchur (2018), Huebener (2019), Kunchur and Knight (2003), Misko et al. (2007) and Vodolazov (2020). This chapter presents (i) a summary of the different FFI models with emphasis on the links between them, (ii) an outline of the vortex-pinning effects on FFI and the associated *paradigm shift* from *global* (Bezuglyj and Shklovskij, 1992; Larkin and Ovchinnikov, 1975; Larkin and Ovchinnikov, 1986) to *local* (Bezuglyj et al., 2019; Vodolazov, 2019) FFI models, and (iii) some of the prospective directions in the fast dynamics research.

Flux-flow instability models

Flux-flow instability mechanisms

Theoretical foundations for understanding of the electronic nonequilibrium effects were laid by Eliashberg (1970) and Eliashberg and Ivlev (1986). Due to external energy input, the quasiparticle energy distribution is modified with respect to equilibrium, which affects the superconducting parameters such as critical temperature T_c , critical current I_c , and superfluid density, and can even result in their enhancement (Wyatt et al., 1966). For instance, the quasiparticle energy distribution can be modified via irradiation with light, microwaves, phonons, injection of quasiparticles, etc. (Gray, 1981).

Experimental studies of the photon absorption response and the effects of high-frequency irradiation of superconductors are usually performed at zero external magnetic field (Natarajan et al., 2012; Zolotarevskii, 2013). By contrast, nonequilibrium effects in the mixed state and the vortex motion under intense transport currents and FFI are studied in the presence of external magnetic fields (Gray, 1981).

The FFI mechanisms are distinct at high ($T \approx T_c$) and low ($T \ll T_c$) temperatures, see Fig. 1C. Close to T_c , FFI can be described by the Larkin-Ovchinnikov (LO) theory (Larkin and Ovchinnikov, 1975; Larkin and Ovchinnikov, 1986). In the LO theory, FFI is associated with a shrinking of the moving vortex and a reduction of the viscosity of the superconducting medium due to the diffusion of quasiparticles from the vortex core to the surroundings. Well below T_c , the LO mechanism is ineffective since in this case the superconducting energy gap Δ does not depend strongly on small changes of the electron distribution function.

At $T \ll T_c$, FFI is described within the framework of the Kunchur (K) hot-electron model in which the electronic temperature T_e is elevated due to dissipation. The higher T_e stipulates the creation of additional quasiparticles, which diminishes Δ . This leads to an expansion of the vortex core (Kunchur et al., 2001; Kunchur et al., 2002), which has the effect of reducing the viscous drag because of the softening of gradients of the vortex profile (Kunchur, 2002).

The LO model (Larkin and Ovchinnikov, 1975) is justified when the inelastic electron-electron scattering time τ_{ee} is much larger than the electron-photon scattering time τ_{ep} , $\tau_{ee} \gg \tau_{ep}$, which ensures a *non-thermal* electron energy distribution. By contrast, $\tau_{ee} \ll \tau_{ep}$ in the K model implies a *thermal-like* electron distribution so that the electronic ensemble exhibits a shift of the electronic temperature T_e with respect to the phonon temperature T_p (Kunchur et al., 2001).

Quasiparticle scattering mechanisms

Standard estimates (Abrikosov, 1988; Kaplan et al., 1976) for the scattering rates $\tau_{ee}^{-1} = k_B T^2 / r \hbar \varepsilon_F$ and $\tau_{ep}^{-1} = k_B T^3 / r^3 \hbar T_D^2 [\varepsilon_F]$: Fermi energy, T_D : Debye temperature] give a crossover temperature $T_x = r^2 k_B T_D^2 / \varepsilon_F$. Here, $r < 1$ is the phonon reflection coefficient at the film-substrate interface, arising from their acoustic mismatch. Thus, one has $\tau_{ee} > \tau_{ep}$ above T_x which can be viewed as a crossover temperature between the K and LO models, see Fig. 1D.

For the classical superconductors, the electron-phonon interaction is usually dominant compared to the electron-electron interaction (Aronov and Spivak, 1978). By contrast, the electron-electron interaction is more important in materials with a high T_D and in high- T_c superconductors (Doettinger et al., 1997). For instance, $T_x \simeq 1$ K for Nb makes accessible both K and LO regimes (Leo et al., 2011). By contrast, $T_x \simeq 100$ K for YBCO points to the dominating electron-electron scattering in the entire temperature range of the superconducting state (Knight and Kunchur, 2006). Finally, $T_x \simeq 0.5$ K for amorphous superconductors like MoGe (Liang and Kunchur, 2010) suggests that the LO mechanism dominates in a broad range of temperatures of the superconducting state.

Larkin-Ovchinnikov model of FFI

The key point of the LO theory (Larkin and Ovchinnikov, 1975; Larkin and Ovchinnikov, 1986) is illustrated in Fig. 2A. At high vortex velocities, the quasiparticles within the vortex core are accelerated toward the core boundary, where they undergo Andreev reflection (Andreev, 1964; Blonder et al., 1982; Octavio et al., 1983) and alternate between electrons and holes. As a result, their energy increases and they eventually escape from the vortex core. This leads to a shrinking of the vortex core and the vortex viscosity η becomes a nonmonotonic function of the velocity v , namely $\eta(v) = \eta(0)/[1 + (v/v^*)^2]$ (Larkin and Ovchinnikov, 1975; Larkin and Ovchinnikov, 1986), so that the viscous force $F_v = \eta(v)v$ has a maximum at v^* . At velocities exceeding v^* , F_v decreases, leading to an even further increase of v , causing an instability in the vortex motion.

The nontrivial nature of the LO effect should be emphasized especially. If one uses the Bardeen-Stephen expression (Bardeen and Stephen, 1965) for $\eta = \Phi_0^2 / (2\pi \xi^2 \rho_n)$ [Φ_0 : magnetic flux quantum, ξ : coherence length, ρ_n : resistivity in the normal state], one finds that it actually *increases* if the size of the vortex core ($\sim 2\xi$) decreases. By contrast, in the LO model, the vortex core shrinks and this

Fig. 2 Schematics of the vortex core shapes in the LO (Klein et al., 1985; Larkin and Ovchinnikov, 1975) and VP (Vodolazov and Peeters, 2007) models assuming spatially uniform and nonuniform nonequilibrium quasiparticle distributions, respectively. (A) The electric field generated by fast vortex motion raises the energy of the quasiparticles trapped in the core. During this process the particle character alternates between electron-like and hole-like due to Andreev reflections. The vortex core shrinks in consequence of the quasiparticle escape. (B) Deformation of the vortex core due to vortex motion. The color depth indicates the density of the quasiparticles. In case the quasiparticle diffusion length is smaller than ξ , diffusion of the quasiparticles is not strong and locally there is an effective cooling and heating of the quasiparticles.

results in a decrease of η . This contradiction can be explained by the failure of the Bardeen-Stephen model for the vortex as a normal cylinder with radius of the order of ξ when the vortex is moving with a high enough velocity v .

The essential assumption of the LO theory is a *spatially uniform* nonequilibrium quasiparticle distribution function $f(E)$ in the superconductor. Accordingly, while the vortex core shrinks as the vortex is accelerated to high velocities, its shape remains *axially symmetric* in the LO model, see Fig. 2A. Moreover, FFI nucleates at all points of the superconductor at the same time and this leads to a *field-independent* v^* at which FFI occurs, see Fig. 1B. Thus, all refinements of the LO model dealing with the spatially uniform nucleation of FFI can be termed *global* FFI models.

Refinements of the Larkin-Ovchinnikov model

Early experiments on low- T_c superconductors confirmed the LO prediction of FFI (Klein et al., 1985; Musienko et al., 1980; Volotskaya et al., 1992). It was revealed that FFI occurs at magnetic fields $B \lesssim 0.7B_{c2}$ (Babic et al., 2004), where B_{c2} is the upper critical field of the superconductor. From the good quantitative agreement between theory and experiment in large magnetic fields, it was concluded (Klein et al., 1985; Musienko et al., 1980) that the condition of spatially uniform $f(E)$ is well satisfied when the distance between vortices $a(B) \simeq \sqrt{\Phi_0/B} \ll L_e \equiv v^* \tau_e$ [L_e : quasiparticle diffusion length, τ_e : quasiparticle energy relaxation time].

However, at $B \ll B_{c2}$, $v^*(B) \sim \sqrt{1/B}$ was observed in many experiments (Doettinger et al., 1994; Doettinger et al., 1995; Lefloch et al., 1999), see Fig. 1B. The observed dependence was explained as a consequence of the crossover from a uniform to a *nonuniform* distribution of nonequilibrium quasiparticles when $L_e = \sqrt{D\tau_e}$ [D : electron diffusion coefficient] becomes comparable with the intervortex distance, $v^* \tau_e \simeq a(B)$. Doettinger et al suggested (Doettinger et al., 1995) that at smaller fields the system can be recovered to a spatially homogeneous state by allowing v^* to grow accordingly to the increase of a with decrease of the applied magnetic field, $a = (2\Phi_0/\sqrt{3}B)^{1/2}$. The LO expression was complemented (Doettinger et al., 1995) with the term $a/\sqrt{D\tau_e}$, yielding

$$v^* = \left[\frac{(1-t)^{1/2} D [14\zeta(3)]^{1/2}}{\pi \tau_e} \right]^{1/2} \left(1 + \frac{a}{\sqrt{D\tau_e}} \right), \quad (1)$$

where $t = T/T_c$ and $\zeta(x)$ is the Riemann function. Note that a $v^*(B) \propto 1/\sqrt{B}$ dependence appears in other FFI models as well.

In the original LO theory, the nonlinear flux-flow behavior is due only to the *electric field-induced* change in $f(E)$ and not Joule heating. Bezuglyj and Shklovskij (BS) extended the LO theory in the thin-film configuration by taking into account *Joule heating* effects (Bezuglyj and Shklovskij, 1992). BS found that even if the Joule heating of the lattice is negligible, quasiparticles can still experience an overheating due to the finite heat removal rate of the power dissipated in the sample which can trigger FFI. Thus, in the BS model, $f(E)$ depends on the *vortex density* and the *rate of heat removal* from the film to the substrate. BS used the electronic temperature approximation, i.e. the assumption that the quasiparticles temperature T_e is uniform throughout the film thickness due to a high electron thermal conductivity. Thus, if the film thickness d is much smaller than the electron-phonon scattering length (that usually occurs in thin films), the nonequilibrium phonons can escape from the film without re-absorption leading to the electron overheating (Bezuglyj and Shklovskij, 1992).

BS introduced a transition magnetic field B_t , see Fig. 1C, which depends on the heat transfer coefficient between the film and the substrate (Bezuglyj and Shklovskij, 1992). At fields $B < B_t$ the hypothesis of a uniform quasiparticles distribution in the LO model remains justified. By contrast, at $B \gg B_t$ dissipation during the flux flow raises the electronic temperature T_e and the onset of FFI is governed by thermal effects. The BS model yields $v^*(B) \propto B^{-1/2}$, see Fig. 1B. Note just the same dependence $v^*(B) \propto B^{-1/2}$ is found in the K model (Kunchur et al., 2001) at $T \ll T_c$ in which thermal effects diminish the superconducting order parameter and lead to an expansion of the vortex cores. However, in the low-temperature regime, the quasiparticles heating reduces B_{c2} to $B_{c2}(T_e) < B_{c2}$.

Quasiparticle relaxation in dirty and clean regimes

The schematics of the vortex core in Fig. 2A allows one to consider distinct quasiparticle energy relaxation processes for dirty and clean superconductors (Peroz and Villard, 2005). When the mean electron free path l is shorter than the coherence length (dirty limit, $l < \xi$), the energy relaxation occurs via the *scattering process inside the vortex core*. In the opposite case (clean limit, $l > \xi$) the quasiparticles can relax their energy by *recombination outside the vortex core* only after covering a distance within the core equivalent to several ξ .

In the microscopic picture where the quasiparticle energy rise comes from Andreev reflections (Andreev, 1964; Blonder et al., 1982; Octavio et al., 1983) at the vortex core boundary, see Fig. 2A, an increase of the quasiparticles energy occurs well below v^* in clean samples so that v^* values in the clean limit are noticeably smaller than in the dirty limit (Peroz and Villard, 2005). Indeed, in the dirty limit, more energy is needed to induce the depletion of quasiparticles of the core. The shrinking of the vortex core occurs at higher energy and τ_e is substantially *temperature independent*. In the clean limit, the quasiparticle distribution function is influenced by the recombination of quasiparticles to Cooper pairs. This means that in the clean limit τ_e is strongly *temperature dependent* since the quasiparticles recombination mechanism obeys an *exponential law* (Doettinger et al., 1997; Liang and Kunchur, 2010; Peroz and Villard, 2005).

High- T_c superconductors and ultraclean regime

FFI was also extensively investigated for high-temperature superconductors (HTSs). These studies were performed for epitaxial (Cherpak et al., 2014; Doettinger et al., 1994; Doettinger et al., 1995; Xiao and Ziemann, 1996), vicinal (Puica et al., 2012) and He ion-irradiated (Xiao et al., 1996) $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ films, MgB_2 (Kunchur et al., 2003), $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ (Xiao et al., 1998), $\text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_{4-x}$ (Doettinger et al., 1997), $\text{Nd}_{2-x}\text{Ce}_x\text{CuO}_y$ (Huebener et al., 1999; Stoll et al., 1999; Stoll et al., 1998) films and $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ nanowires (Lyatti et al., 2018; Rouco et al., 2018). The distinct effects of intrinsic (nonequilibrium) and extrinsic (thermal runaway) mechanisms driving FFI were discussed for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ films (Maza et al., 2008) and for iron based superconductors (Leo et al., 2016). Signatures of FFI in the anisotropic FeSeTe have allowed for its treatment halfway between low- T_c and high- T_c superconductors.

In the dirty limit, the energy distribution of the quasiparticles in the vortex core is strongly smeared out due to their high scattering rate. The separation between the quasiparticles energy levels and between the Fermi energy ξ_F and the lowest bound state in the vortex core is proportional to ξ^{-2} (Huebener, 2019). With an estimate $\xi \lesssim 10$ nm for disordered low-temperature superconductors (Córdoba et al., 2019; Korneeva et al., 2020; Porrati et al., 2019), the core can be treated as an energy continuum of quasiparticles. By contrast, the extremely small $\xi \lesssim 1$ nm in the HTS cuprates makes the *electron quantum structure* of the vortex core essential. For its experimental observation, the energy smearing $\delta\varepsilon = \hbar/\tau$ due to the mean electronic scattering time τ must be sufficiently small, $\delta\varepsilon \ll \Delta^2/\varepsilon_F$, corresponding to the ultraclean superconducting limit. Such a regime has been experimentally realized in Huebener et al. (1999), Stoll et al. (1999) and Stoll et al. (1998). Proceeding from an isolated vortex to the vortex lattice, the discrete energy levels within the vortex core interact between neighboring vortices and broaden into *mini-bands* (Huebener, 2019). In this case, vortex motion at high velocities is accompanied by emerging phenomena, such as Bloch oscillations of the quasiparticles, negative differential resistance, and multi-step instabilities (Huebener, 2019; Huebener et al., 1999; Stoll et al., 1999; Stoll et al., 1998).

Pinning effects on the flux-flow instability

Effects of uncorrelated disorder on FFI

The LO model considered a moving vortex lattice in an infinite superconductor in the Wigner-Seitz approximation and ignored collective effects related to vortex pinning and lattice transformations. The assumption of no pinning corresponds to a δ -functional velocity distribution in the vortex ensemble and a free flux flow with zero critical current (Liang et al., 2010). In this case, an increase of current produces a shift of the velocity distribution to higher mean values $\langle v \rangle$ until the vortex instability occurs at v^* for all vortices *simultaneously*. Note, it is the *mean value* $\langle v \rangle$ which is deduced from the dc voltage measured experimentally.

In disordered systems, a rather narrow distribution of vortex velocities, see Fig. 3A, can be realized in a *weak-pinning* regime or at high enough fields and currents such that the vortex-vortex interaction is stronger than the vortex-pinning interaction (Blatter et al., 1994). In particular, an increase of the current I above I_c produces a shift of the velocity distribution toward higher mean values $\langle v \rangle$ and progressively *narrows* the distribution peak in consequence of the enhanced long-range order in the moving vortex lattice (Koshelev and Vinokur, 1994). The FFI jump occurs at the end of the quasilinear flux-flow regime, see Fig. 3B. The commonly occurring vortex dynamics regimes are indicated in Fig. 1A.

The introduction of *strong pinning* by *uncorrelated disorder* substantially modifies the previous picture (Leo et al., 2010; Ruck et al., 2000; Shklovskij et al., 2017; Silhanek et al., 2012). As pointed out by Silhanek et al. (2012), on the one hand, the presence of disorder broadens the velocity distribution and extends the nonlinear regime for currents above the critical value I_c (Grimaldi et al., 2009b). This is schematically shown in Fig. 3C and D. On the other hand, strong pinning increases I_c and causes FFI to occur within the depinning-mediated nonlinear section of the I - V curve. Importantly, the broadening of the velocity distribution implies a *sizeable separation* between $\langle v \rangle$ and the maximal attainable vortex velocity v^* . This means that it is the vortices which move faster than other vortices in the ensemble which actually trigger FFI. Once FFI is triggered in the regions of faster-moving vortices it is then spread over the entire volume of the superconductor.

Fig. 3 Schematic representation of different dynamic regimes after Silhanek et al. (2012). Velocity distribution for the case of flux flow (A) and plastic flow (C). Expected I - V curves for weak (B) and strong (D) pinning strengths. The critical current density I_c indicates the onset of dissipation. The instability current I^* and voltage V^* indicate where FFI takes place.

Thus, in this plastic vortex flow regime, the system reaches the instability point at a *lower* vortex velocity than expected, practically when $v_{\max} \simeq v^*$. In this case, the LO assumption of homogeneous quasiparticle distribution in the whole sample has to be dropped and instead homogeneous quasiparticle distribution only along the paths where the vortices move has to be considered (Silhanek et al., 2012). As the magnetic field increases, the distance between the vortices decreases and the vortex-vortex interaction increases, which in turn effectively diminishes the role of pinning. This narrows the vortex velocity distribution so that v^* increases. With a further increase of the magnetic field, the assumption of homogeneous quasiparticle distribution becomes justified again, and the LO scenario is retained. This gives rise to qualitatively different dependences of $v^*(B)$, see Fig. 1B, and enables controlling the flux-flow dissipation via vortex pinning engineering in superconductors (Grimaldi et al., 2012; Ruck et al., 2000).

Low-field crossover in the instability velocity

A crossover to a different behavior of $v^*(B)$ at magnetic fields $B < B_{\text{cr1}}$ was reported by Grimaldi et al. (2009a) and Grimaldi et al. (2010) for Nb films with moderately strong intrinsic pinning. This field B_{cr1} corresponds to a crossover from the regime where v^* increases with increasing magnetic field to the regime $v^* \propto B^{-1/2}$, see Fig. 1B. Magneto-optical imaging of the flux penetration into the films at $B \ll B_{\text{cr1}}$ revealed that the flux does not penetrate with a smooth advancing front, but instead as a series of irregularly shaped protrusions. This causes the formation of an inhomogeneous magnetic field distribution and induces preferential stationary channels for the moving vortices with a total effective width l (Grimaldi et al., 2010). An inspection of the films by field emission scanning electron microscopy revealed that these channels are grouped together in clusters along the strip (Grimaldi et al., 2010). This means that the voltages measured across the distance L between the voltage leads are actually produced across an *effective* distance $l < L$, so that in the low-field range $B < B_{\text{cr1}}$, the flux-flow channels fill only parts of the whole strip length.

On the contrary, when the flux penetration becomes smooth, above some threshold temperature T^* ($\simeq 0.75T_c$ for the films studied in (Grimaldi et al., 2010)), the pinning strength decreases so the vortex flow becomes uniform as well. In this way, below T^* , the decreasing low-field dependence $v^*(B)$ is preserved, whereas above T^* , the crossover field disappears, leading to a monotonous decrease of $v^*(B) \propto B^{-1/2}$, see Fig. 1B and C. Herewith, B_{cr1} corresponds to a crossover from the channel-like vortex motion to a uniform flux-flow state with increase of the magnetic field. Accordingly, at $T < T^*$, the flux-flow resistance ρ_{ff} assumes lower values than the Bardeen-Stephen prediction while the expected linear $\rho_{\text{ff}}(B) \propto B$ is retained at $T > T^*$ (Grimaldi et al., 2010).

Pinning effects on self-heating and FFI

The effects of pinning and self-heating on FFI in thin films were considered theoretically by Shklovskij et al for the cases $T \ll T_c$ (Shklovskij, 2017) and $T \approx T_c$ (Shklovskij et al., 2017). The problem was considered in the single-vortex approximation, upon the nonlinear I - V curves derived for a saw-tooth (Shklovskij and Dobrovolskiy, 2006) and cosine (Shklovskij and Dobrovolskiy, 2008) pinning potentials.

In the low-temperature regime, within the framework of the K model (Kunchur, 2002), the presence of pinning has been revealed (Shklovskij, 2017) to not modify the magnetic field dependences of the electric field $E^*(B)$, current density $j^*(B)$ and resistivity ρ^* at the instability point, which remain monotonic. By contrast, the derivative of the instability velocity dv^*/dB may change its sign twice, as observed in experiments (Dobrovolskiy et al., 2017b; Grimaldi et al., 2009a; Grimaldi et al., 2011; Grimaldi et al., 2012; Grimaldi et al., 2010; Leo et al., 2010; Leo et al., 2020b; Silhanek et al., 2012). In particular, experiments on weak-pinning 5 μm -wide Mo_3Ge thin films (Leo et al., 2020b) revealed that the observed nonmonotonic $v^*(B)$ dependence can be described well with the theoretical dependences of Shklovskij (2017). For wider films, that is in the absence of the surface pinning caused by the mesoscopic geometry, the experimentally observed (Leo et al., 2020b) dependence $v^*(B) \propto B^{-1/2}$ fits the K model (Kunchur et al., 2001).

In the high-temperature regime, within the framework of the LO theory (Larkin and Ovchinnikov, 1975) and its generalization by BS (Bezuglyj and Shklovskij, 1992), the increase of the pinning strength does not change the field dependences of the electric field strength $E^*(B)$ and the current density $j^*(B)$ qualitatively. At a fixed magnetic field value, E^* and v^* decrease while j^* increases with increasing magnetic field. In this way, the theoretical analysis of Shklovskij (2017) and Shklovskij et al. (2017) corroborates that the presence of pinning leads to a reduction of v^* , with exception of highly-correlated, periodic pinning-induced regimes in the vortex dynamics as outlined next.

Vortex lattice commensurability effects on FFI

In the presence of a periodic pinning, the spatial commensurability between the vortex lattice with the pinning landscape leads to magnetoresistance minima and critical current maxima (Cuadra-Solis et al., 2014; Dobrovolskiy et al., 2020a; Dobrovolskiy et al., 2012; Dobrovolskiy et al., 2018; Dobrovolskiy et al., 2017b; Jaque et al., 2002; Lu et al., 2007; Villegas et al., 2003). In this regime, v^* attains a maximum when the spacing between the rows of vortices driven across an array of nanogrooves is commensurate with the distance between them (Dobrovolskiy et al., 2017b). The location of this matching peak can be tuned through the nanostructure period variation.

The considered case can be realized for nanopatterned superconductors at the fundamental matching field when vortex dynamics is in a coherent regime, i.e., the entire vortex ensemble behaves as a vortex crystal (Cuadra-Solis et al., 2014; Dobrovolskiy et al., 2020a; Lu et al., 2007; Villegas et al., 2003). At the same time, the background pinning due to undesired random disorder must be weak to ensure the long-range order in the vortex lattice in the vicinity of the depinning transition. This condition can be realized, e.g., in weak-pinning amorphous Mo_3Ge (Grimaldi et al., 2015), Nb_7Ge_3 (Babic et al., 2004), MoSi (Budinska et al., 2022), nanocrystalline Nb–C (Dobrovolskiy et al., 2020c), as well as Al (Silhanek et al., 2012) and epitaxial Nb films in the clean superconducting limit (Dobrovolskiy and Huth, 2012).

Fast dynamics of guided magnetic flux quanta

An interesting possibility to enhance the long-range order in the moving vortex lattice is offered by the vortex guiding effect (Dobrovolskiy et al., 2010; Niessen and Weijssensfeld, 1969; Shklovskij and Dobrovolskiy, 2006). This effect consists in the noncollinearity of the velocity of vortices with the driving force exerted on them by the transport current. In the regime of guiding under the action of the driving Lorentz-type force F_L directed at a small tilt angle α with respect to linearly extended “pinning sites”, see Fig. 4A, all vortices move along the pinning channels and the distribution of their velocities is close to the δ -functional shape. The small angle α ensures that the normal component of the driving force $F_L \sin \alpha$ is not large enough to let vortices overcome the potential troughs, while the tangential component $F_L \cos \alpha$ is large enough to drive the vortices at a few km/s velocities (Dobrovolskiy et al., 2019a).

The presence of the vortex velocity component along the sample length in the guiding regime leads to the appearance of a transverse voltage. This voltage vanishes upon a transition from the vortex guiding regime to a regime in which vortices start overcoming the pinning potential barriers (Reichhardt and Reichhardt, 2008; Shklovskij and Dobrovolskiy, 2006). By guiding magnetic flux quanta at a tilt angle of 15 degrees with respect to Co nanostripe arrays deposited on top of Nb films, a fivefold enhancement of v^* (up to 5 km/s at low magnetic fields) was observed experimentally (Dobrovolskiy et al., 2019a). In a different experiment, I – V measurements on tracks perpendicular to the vicinal (8 degrees) step direction of $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ films (current crossed between ab planes) provided evidence for the sliding motion along the ab planes (vortex channeling) at velocities exceeding 8 km/s (Puica et al., 2012).

From global to local instability models

Local FFI model for thin films near T_c

Distinct from the nonlinear conductivity regime considered by LO, FFI jumps were also observed in linear I – V sections (Grimaldi et al., 2011; Volotskaya et al., 1992). A broad distribution of vortex velocities caused by the presence of regions with different pinning strengths is a likely cause for such a regime. Namely, on average, an essentially larger number of slowly moving vortices can make a larger contribution to the measured voltage as compared to the contribution of a much smaller number of faster moving vortices, allowing the I – V curve to maintain a linear shape up to the instability point. The respective local FFI theory was developed

Fig. 4 (A) Schematic of a vortex lattice which is commensurate with a periodic washboard pinning landscape. When the vortices are guided at some tilt angle α with respect to the pinning channels, the long-range order in the vortex lattice is enhanced (Dobrovolskiy et al., 2020a; Dobrovolskiy et al., 2019a). (B) The combination of a weak intrinsic pinning, close-to-depairing critical current and fast relaxation of nonequilibrium allows for ultra-high vortex velocities (Dobrovolskiy et al., 2020c). The nucleation of FFI occurs at the film edge of the film and is decisively controlled by its quality (Budinska et al., 2022; Vodolazov, 2019).

by Bezuglyj et al. (2019), based on the assumption that FFI occurs upon reaching I^* not in the entire superconducting film but in a narrow strip with weak pinning across the film width in which vortices move much faster than outside it.

As a consequence of the overheating of the local areas with faster moving vortices, *normal domains* can be formed *across* the superconducting film. Once the current density exceeds some threshold current density (determining the equilibrium of the non-isothermal normal/superconducting boundary) (Bezuglyj and Shklovskij, 1984; Gurevich and Mints, 1984) these domains begin to grow and the whole sample transits to the normal state (Bezuglyj et al., 2019). In this case, the standard relation $v^* = V^*/(BL)$ can no longer yield the instability velocity quantitatively. Nevertheless, the functional relations between the LO instability parameters in the case of a local FFI remain the same as in the case of a global FFI, but require *renormalization* of the sample length (Bezuglyj et al., 2019).

Rearrangement of vortices in the TDGL model

The LO model assumes that the vortex lattice does not exhibit any structural changes upon the transition of the superconductor to a state with a resistance close to the normal value. However, experiments on low- and high-temperature superconductors suggested that some kind of phase transition may occur in the fast-moving vortex lattice and regions with fast and slow vortex motions may appear in the sample (Adami et al., 2015; Grimaldi et al., 2015).

An alternative view of the moving vortex at high velocities, in which it loses the shape of a rigid cylinder, was used by Vodolazov and Peeters (2007). Reducing the problem to a two-dimensional one, VP solved *numerically* the generalized time-dependent Ginzburg-Landau (TDGL) equations (Kramer and Watts-Tobin, 1978; Watts-Tobin et al., 1981) which take into account the spatially *nonuniform* distribution of quasiparticles as the longitudinal (odd in energy E) part $f_L(E) = f(-E) - f(E)$ of the nonequilibrium $f(E)$ distribution is localized only in the region where the time derivative $\partial|\psi|/\partial t$ is finite, that is only near the moving vortex core, see Fig. 2B.

Indeed, the motion of a vortex implies a suppression of the order parameter ψ in front of the vortex and its recovery behind it. If the vortex velocity is large enough, $v \simeq \xi/\tau_v$, the number of quasiparticles in front of the vortex becomes smaller than the equilibrium value and it becomes larger behind the vortex due to the finite relaxation time of $f(E)$. Effectively, this can be viewed as *cooling* of the quasiparticles in front of the vortex and *heating* behind the vortex. Since the relaxation time of ψ depends on temperature as $\tau|\psi| \sim 1/(T_c - T)$, the healing time of the order parameter behind the vortex is long while the time of the order parameter suppression in front of the vortex is short. This leads to an *elongated shape* of the vortex core with a point where $|\psi| = 0$ displaced in the direction of the vortex motion.

The elongated shape of the core of a fast-moving vortex is in line with the field distribution around it as derived *analytically* based on the time-dependent London (TDL) equation (which ignores the vortex core) (Kogan and Prozorov, 2020). The flux quantum of a moving vortex is redistributed: The back-side part of the flux is enhanced, whereas the in-front part is depleted (Kogan and Nakagawa, 2021). Distortions of the field distribution of single moving vortices lead to distorted intervortex interactions and therefore to a change in the vortex lattice structure (Kogan, 2018). At large velocities, the moving vortex lattice adopts the structure with one of the lattice vectors along the velocity, the same result as obtained within TDGL (Li et al., 2004; Vodolazov and Peeters, 2007).

Edge-controlled FFI in the weak-pinning regime

In the Knight and Kunchur (2006), Kunchur (2002), Shklovskij (2017), Bezuglyj and Shklovskij (1992) and Shklovskij et al. (2017) models the temperature of the electrons T_e was calculated from the balance between the spatially- and time-averaged Joule dissipation and the heat removal to the substrate, which ignores the discrete nature of the moving vortices. Vodolazov (2019) solved the TDGL equation in conjunction with the heat conduction equation for T_e and the energy balance equation to find the phonon temperature T_p , which were derived from the *kinetic equations* for the electron and phonon distribution functions (Vodolazov, 2017).

In the V model, in the low-resistive state, there is a temperature gradient across the width of the strip with maximal local temperature near the edge where vortices enter the sample (Vodolazov, 2019). The higher temperature at the edge is caused by the larger current density in the near-edge area due to the presence of the *edge barrier* for vortex entry and, hence, the locally larger Joule dissipation. With increase of the current, there is a series of *transformations* of the moving vortex lattice in the V model.

At $I \lesssim I^*$, localized areas with strongly suppressed superconductivity and closely spaced vortices appear near the hottest edge (left edge in Fig. 4B). Upon reaching I^* , these areas begin to grow in the direction of the opposite edge and form highly resistive Josephson SNS-like links—*vortex rivers*—along which the vortices move. Such vortex rivers were observed experimentally by scanning local probes (Embon et al., 2017; Silhanek et al., 2010). Due to the increasing dissipation, vortex rivers evolve into normal domains which then expand along the strip (Dobrovolskiy et al., 2020c).

Distinct from the modified LO model (Doettinger et al., 1995), in the V model $v^* \sim B^{-1/2}$ only at comparatively large magnetic fields (see Fig. 1B), when the intervortex distance at $I \simeq I_c$ and $I \simeq I^*$ is almost the same despite the transformations in the moving vortex lattice. By contrast, at relatively small magnetic fields, a in the vortex rows is smaller than $(2\Phi_0/B\sqrt{3})^{1/2}$ at $I \simeq I^*$ and the number of vortices n is smaller than follows from $n\Phi_0 = BS$ [S : sample area]. This leads to a weaker dependence $v^*(B)$ than $v^* \sim B^{-1/2}$ following from “global” instability models. This behavior is confirmed experimentally (Dobrovolskiy et al., 2020c).

Edge barrier effects on the fluxon speed limits

The prediction (Vodolazov, 2017) and experimental confirmation (Charaev et al., 2020; Chiles et al., 2020; Korneeva et al., 2020; Korneeva et al., 2018) of the single-photon detection capability of micrometer-wide strips has turned FFI into a widely used method for judging whether a superconducting material could be potentially suitable for single-photon detection (Caputo et al., 2017; Cirillo et al., 2021; Dobrovolskiy et al., 2020c; Lin et al., 2013). This assessment is based on the deduction of the quasiparticle relaxation times from FFI. However, while many dirty superconductors (NbN (Korzh et al., 2020), MoSi (Korneeva et al., 2020), NbRe (Cirillo et al., 2020), NbReN (Cirillo et al., 2021), etc.) possess good single-photon detection capability, v^* and τ_e deduced from FFI are not always consistent with the fast relaxation processes implied by photon-counting experiments (Budinska et al., 2022).

The edge quality turns out to be decisive for the nucleation of FFI and, hence, quantification of the relaxation times from the I - V measurements (Budinska et al., 2022). By investigating FFI in wide MoSi strips differing only by the edge quality, a factor of 3 larger critical currents I_c , a factor of 20 higher maximal vortex velocities of 20 km/s, and a factor of 20 shorter τ_e have been revealed for MoSi films with perfect edges. Thus, for the deduction of the intrinsic τ_e of the material from the I - V curves, utmost care should be taken regarding the edge and sample quality, and such a deduction is justified only if the field dependence of I_c points to the dominating edge pinning of vortices (Budinska et al., 2022).

Edge defects as gates for fast-moving fluxons

The requirement of close-to-depairing critical currents I_c in superconductor strips is related to blocking of the penetration of vortices via the strip edges and knowledge of the effects of various edge defects on the penetration and patterns of Abrikosov vortices (Aladyshkin et al., 2001; Glazman, 1986; Sivakov et al., 2018; Vodolazov et al., 2015; Vodolazov et al., 2003). Once the Lorentz force exerted on a vortex by the transport current exceeds the force of attraction of the vortex to the sample edge, the edge barrier is suppressed. This suppression can be local in the case of a local increase of the current density—*current-crowding* effect (Adami et al., 2013), and it can be realized, e.g., in strips with an edge defect (Budinska et al., 2022; Dobrovolskiy et al., 2020c). In this case, the

defect acts as a gate (Aladyshkin et al., 2001) for vortices entering into the superconductor strip and crossing it under the competing action of the Lorentz and vortex-vortex interaction forces.

If the size of the defect is much larger than ξ , the defect can serve as a nucleation point for several vortex chains (Budinska et al., 2022; Embon et al., 2017). Such chains form a *vortex jet* with the apex at the defect and expanding due to the repulsion of vortices as they move to the opposite film edge. If the defect size is $\simeq \xi$, the vortices enter into the strip consequentially. However, in the presence of fluctuations and inhomogeneities in the strip, the vortex chain evolves into a diverging jet because of the intervortex repulsion.

Vortices penetrating into a superconducting Pb film at rates of tens of GHz and moving with velocities of up to tens of km/s were observed by scanning SQUID-on-tip (SOT) microscopy (Embon et al., 2017). Though these vortices move faster than the perpendicular current superflow which drives them, no excessive changes in the structure of the Abrikosov vortex core has been revealed even at velocities of the order of 10 km/s (Embon et al., 2017). Because of the large current density gradient across the constriction with narrowing, a vortex chain splits up into a fan-like pattern of slipstreaming vortices. The TDGL modeling suggested that the slipstreaming vortices could further evolve to Josephson-like vortices moving with velocities as high as ~ 100 km/s (Embon et al., 2017). Spatial modulation of the order parameter between these vortices is rather weak and the channel behaves effectively as a self-induced Josephson junction, which appears without materials weak links. Such flux channels in thin films can be interpreted as phase-slip lines (Sivakov et al., 2003).

Vortex jet shapes have recently been analyzed based on the dynamic equation (Bezuglyj et al., 2022). For wide strips (width w much larger than the penetration depth λ), the analytically calculated vortex jet shapes reproduce qualitatively the experiment (Embon et al., 2017). For narrow strips ($\xi \ll w < \lambda$), the discrete TDGL approach reveals dynamic transitions from a vortex chain to a vortex jet and, at $I \lesssim I^* \simeq I_d$, from the vortex jet to a vortex river (Bezuglyj et al., 2022).

Fast vortex dynamics under a microwave ac stimulus

Enhancement of superconductivity at microwaves

Microwave irradiation is being used to control the quantum properties of different systems, ranging from supercurrents in superconductors to mechanical oscillators (Barzanjeh et al., 2022; Bergeret et al., 2010; Clerk et al., 2020; McIver et al., 2012; Palomaki et al., 2013). Nowadays, using nonequilibrium pumping for cooling is a hot topic (Bhadrachalam et al., 2014; Fornieri and Giazotto, 2017; José Martínez-Pérez and Giazotto, 2014; Maillet et al., 2020; Schneider et al., 2020; Uroš et al., 2020). In 1966, microwave stimulated superconductivity (MSSC) was discovered in superconducting bridges (Wyatt et al., 1966) and later confirmed for different type I superconducting systems (Beck et al., 2013; Dayem and Wiegand, 1967; de Visser et al., 2014; Heslinga and Klapwijk, 1993; Pals and Dobben, 1979; Pals and Dobben, 1980; Tolpygo and Tulin, 1983). It was later found that also acoustic waves (Tredwell and Jacobsen, 1975) and tunneling injection currents may, under certain conditions, cause an increase of the gap in the excitation spectrum, the order parameter, the critical current and the critical temperature T_c (Gray, 1981).

The phenomenon of MSSC was explained by Eliashberg (1970) as a consequence of an irradiation-induced redistribution of quasiparticles away from the gap edge. Namely, in the BCS theory, there is a fundamental connection between the gap value Δ and the occupation of the quasiparticle states (Bardeen et al., 1957; Tinkham, 2004). When the temperature is increased from zero, more and more quasiparticles are excited blocking states which were previously available for Cooper pair formation. Ultimately this process leads to the disappearance of superconductivity at T_c . Extraction of quasiparticles leads to enhancement of superconductivity but is elusive to realize. However, there is another possibility. Electron states near the Fermi surface are more important to Cooper pair formation than states further away from it. If a quasiparticle in a state near ε_F is removed to a state with higher energy, the energy gap increases, although the total number of quasiparticles remains constant. This is the essential basis of the E mechanism. In a microwave field, the quasiparticles are “pumped up”, away from the gap. Even if the average energy of the quasiparticles increases, the gap is enhanced. Recent reviews on MSSC are given in Klapwijk and de Visser (2020) and Tikhonov et al. (2020).

Condensate and quasiparticles under dc/ac biasing

The vortex state is characterized by a spatially modulated superconducting order parameter which vanishes in the vortex cores and attains a maximal value between them. Accordingly, a type II superconductor can be regarded as a continuum medium consisting of bunches of quasiparticles in the vortex cores surrounded by a bath of the superconducting condensate formed by the superfluid of Cooper pairs. So far there is no available theory addressing the complex interaction of the superimposed dc and microwave currents with the quasiparticles and the condensate at the same time. However, the essential ingredients of this interaction have been studied separately.

The effect of a dc current on the superconducting condensate is well known (Anthore et al., 2003). With an increase of a dc current, the absolute value of the order parameter is decreasing and the peak in the density of states at the edge of the superconducting gap is smeared, see Fig. 5A. This is because of gaining a finite momentum by the Cooper pairs that form a coherent excited state that plays a central role in the explanation of the gauge invariance of the Meissner effect (Anderson, 1958). A general theory of depairing by a microwave field has been formulated recently (Semenov et al., 2016), under the condition of rather small ac

Fig. 5 (A) Schematics of the modification of the electronic distribution function $f(E)$ in the presence of a microwave excitation after (Tikhonov et al., 2018). The redistribution of the quasiparticles between the $\Delta - \hbar\omega$ and $\Delta + \hbar\omega$ states leads to a higher inclination of $f(E)$ at the Fermi energy level ϵ_F , which can be viewed as an effective “cooling”. (B) Time-averaged density of states in a dirty superconductor at low temperature ($T \ll T_c$) under different biasing after (Semenov et al., 2016; Tikhonov et al., 2020). The value of the current or its amplitude is $0.25I_c$.

field amplitudes. It has been shown that the ground state of a superconductor is altered qualitatively in analogy to the depairing due to a dc current. However, in contrast to dc depairing, the density of states acquires steps at multiples of the microwave photon energy and shows an exponential-like tail in the subgap regime (Semenov et al., 2016). Additionally, depending on temperature, one can consider two regimes in which the response of a superconductor is dominated either by the response of the superfluid ($T \leq T_c$) or by the quasiparticles ($T \approx T_c$). It is also known that at $T \approx T_c$, microwave radiation can be absorbed by quasiparticles, leading to a nonequilibrium distribution over the energies (Eliashberg, 1970), see Fig. 5B.

In general, the response of the condensate to an external microwave field becomes apparent via a change of the kinetic impedance (imaginary part of the complex resistivity) while the quasiparticles give rise to the microwave loss (real part of the complex resistivity). The known effects of stimulation of superconductivity by a microwave stimulus in the absence of an external magnetic field include an enhancement of the Ginzburg-Landau depairing current (in narrow channels) implying a transition to a resistive state due to the formation of phase-slip centers (Zolotarevskii, 2013) or the Aslamazov-Lempitskii maximum current (in wide films) at which the vortex structure induced by the self-field evolves into the first phase-slip line (Aslamazov and Lempitskii, 1982). In the presence of an external magnetic field inducing vortices in the superconductor, the vortex-induced microwave losses dominate the response of the superconductor (Pompeo and Silva, 2008).

Microwave stimulation in the vortex state

From Fig. 5A it follows that a dc current leads to a smearing of the BCS peak at the gap edge. Further, the presence of vortices leads to a strongly spatially non-uniform order parameter (with normal-state regions inside the vortex cores). Moreover, the motion of current-driven vortices leads to dissipation (Brandt, 1995; Pompeo and Silva, 2008). All together, these circumstances diminish the stimulation effect of the microwave excitation. Nonetheless, in the regime of low vortex densities and for superconductors with

rather slow relaxation of nonequilibrium quasiparticles, the stimulation of superconductivity under a microwave ac stimulus can be observed in the presence of vortices (Dobrovolskiy et al., 2019b; Lara et al., 2015).

Note, the dynamics of vortices under a microwave ac stimulus differs qualitatively from the dc-driven vortex motion. Namely, while a moderately strong dc transport current (i.e., when the current-induced Lorentz-type force exceeds the pinning force (Brandt, 1995)) causes a *translational* motion of vortices, a microwave ac current *shakes* the vortices. Accordingly, in the presence of pinning sites, one can distinguish between the low-frequency and high-frequency regimes in the vortex dynamics. Namely, when the ac half-period is long enough, a vortex can move over *many* pinning sites, while in the high-frequency regime a vortex is shaken in vicinity of *one* pinning site. The crossover between the two regimes occurs at the so-called *depinning frequency* f_d (Coffey and Clem, 1991; Dobrovolskiy et al., 2015; Gittleman and Rosenblum, 1966; Pompeo and Silva, 2008; Shklovskij and Dobrovolskiy, 2008; Shklovskij et al., 2014). In the low-frequency regime, the pinning forces dominate and the vortex response is weakly dissipative. By contrast, in the high-frequency regime, the oscillating vortices cease to feel the detail of the pinning potential, the frictional forces prevail, and the response is strongly dissipative. Note, this consideration is justified for short vortices in thin films and it is inapplicable to thick films where long vortices can get elastically distorted extending over many pinning sites (Pathirana and Gurevich, 2021).

The depinning frequency depends on temperature $f_d(T, H, I) \simeq f_d(0, H, I)[1 - (T/T_c)^4]$ (Alimenti et al., 2020; Zaitsev et al., 2003), magnetic field $f_d(T, H, I) \simeq f_d(T, 0, I)[1 - (H/H_{c2})^2]$ (Alimenti et al., 2020; Janjušević et al., 2006) and the dc current as $f_d(T, H, I) \simeq f_d(T, H, 0)[1 - (I/I_d)^m]^n$ with the exponents m between 3/2 and 4 and n between 1/4 and 2/3, depending on the details of the pinning potential (Dobrovolskiy et al., 2017a). At relatively low excitation power levels, for a commensurate vortex lattice in a periodic pinning landscape, ac losses due to ac-driven vortex oscillations are minimal because of the enhanced efficiency of the pinning (Dobrovolskiy et al., 2020a; Dobrovolskiy and Huth, 2015). By contrast, a qualitatively different behavior is observed when the microwave power increases beyond a certain, frequency-dependent power level: the microwave losses are maximal for pinned vortices, and they are minimal for depinned vortices (Dobrovolskiy et al., 2019b; Lara et al., 2015). In this nonlinear regime, the vortices act as “relaxators” rather than rigid “oscillators”. Since quasiparticles escape from the vortex cores, their escape can be seen as an effective decrease of the amplitude of the vortex oscillations with increase of the ac frequency.

Braking of instabilities by a microwave stimulus

The FFI onset can be advanced or delayed in the presence of superimposed dc and ac current drives (Cherpak et al., 2014; Dobrovolskiy et al., 2020b). Namely, in the presence of a dc current, an abrupt transition to a high-loss state occurs at lower microwave power levels (Cherpak et al., 2014). The addition of an ac stimulus on top of a dc current allows for tuning the FFI onset (Dobrovolskiy et al., 2020b), see Fig. 6A, depending on the ac power P and frequency f . Thus, when the ac power exceeds some threshold value P_{st} , at high enough (GHz) ac frequencies the quasilinear flux-flow regime can be extended up to a higher current I_{mw}^* , whereas the FFI occurs at a smaller I_{mw}^* in the presence of a low-frequency ac current (Dobrovolskiy et al., 2020b). With a

Fig. 6 (A) Evolution of the instability current $f \leq f_d$ for a Nb film at $T = 0.998 T_c$ and $H = 10$ mT in a broad range of frequencies and power levels of the ac stimulus. I^* : instability current value without microwave stimulus. (B) The sketch illustrates the overlap of the regions where vortices move under a microwave ac field of different powers and frequencies. As the vortices move, their radii change. This could lead the heated zones to overlap and produce avalanches.

further increase of the ac power, the heating will dominate the cooling effect and the FFI will occur at a smaller I_{mw}^* . This behavior can be explained, qualitatively, based on a model of “breathing mobile hot spots”, implying a competition of heating and cooling of quasiparticles along the trajectories of moving fluxons whose core sizes vary in time. This breathing mode appears owing to the variation of the vortex core sizes in time due to the periodically modulated quasiparticle escape from the cores. Accordingly, the strong oscillations of vortices lead to the formation of “clouds” of quasiparticles around the vortex cores, whose relaxation takes place in a larger volume as compared to the non-excited case. Thus, dissipation is decreasing due to the combined effects of the redistribution of quasiparticles away from the gap edge via the Eliashberg mechanism and the relaxation of the quasiparticles in larger volumes around the vortex cores. A theory of MSSC at high vortex velocities is yet to be elaborated.

Instabilities can also occur in superconductors when the flux is getting redistributed upon temperature or magnetic field variation (Altshuler and Johansen, 2004; Aranson et al., 2005; Colauto et al., 2021; Mints and Rakhmanov, 1981). Herewith, vortex penetration may occur either smoothly or in sudden bursts, giving rise to *thermomagnetic instabilities*. In the case of smooth penetration, the flux density inside the superconductor changes gradually, being described by a *critical state model* (Bean, 1962; Kim et al., 1963; Zeldov et al., 1994). However, when the penetration is abrupt, narrow branches of flux, in the form of dendrites, invade the sample. The critical state model is no longer appropriate to describe this case.

In a typical critical state type of flux distribution, millions of vortices self-organize, under the competing vortex-vortex repulsion, Lorentz and pinning forces. This delicate balance results in metastable states between which sudden flux redistributions occur. These *flux avalanches* occur typically during a slow ramping of the applied magnetic field, and at temperatures below a certain fraction of T_c . The flux patterns are never reproduced when experiments are repeated, thus ruling out possible explanations based on material defects guiding the flux motion (Colauto et al., 2021). The thermomagnetic instability or flux jumping arises because of two fundamental reasons (Denisov et al., 2006): (i) motion of magnetic flux releases energy, and hence increases the local temperature; (ii) the temperature rise decreases flux pinning, and hence facilitates the flux motion. This positive feedback can result in thermal runaways and global flux redistributions jeopardizing superconducting devices.

According to the model based on thermomagnetic instabilities (Rakhmanov et al., 2004), an avalanche is triggered by a thermal fluctuation (hot spot), which facilitates more flux motion toward the hot place, with a subsequent heat release. Under quasi-equilibrium conditions, the avalanches can also be triggered by microwave pulses (Cuadra-Solis et al., 2013) or ac signals at near resonant frequencies of superconducting cavities (Chigo et al., 2007). Under a broadband microwave field sweep, flux avalanches are triggered at different depinning frequencies due the distribution in strength of individual vortex pinning sites (Awad et al., 2011).

At I_{mw}^* , flux avalanches exhibit a thermally driven behavior since higher temperatures facilitate the entrance of magnetic flux and enhance the vortex mobility. Accordingly, the critical microwave power P_c for triggering an avalanche monotonously decreases with approaching T_c . However, at $f \simeq f_d$, the behavior of $P_c(T)$ inverts, demonstrating a thermally driven avalanche *inhibition* (Lara et al., 2017). This effect can be understood as a consequence of the dependence of the vortex core size on P and f . Namely, at $f \lesssim f_d$, the LO effect manifests itself only in the regions of maximal velocity (i.e., close to displacement minima), see panel 1 in Fig. 6B. On the other hand, at $f \simeq f_d$, the vortices become more mobile. As a result, the LO reduction of the vortex core manifests itself during the whole displacement cycle, see panel 2 in Fig. 6B. Below f_d and at low P , local “normal” regions created by the driven vortices do not overlap and are not sufficient to trigger the avalanche process.

Increasing the microwave power below f_d enhances the absolute changes in the vortex core size, inducing the overlap between different extended core areas and triggering the avalanche at $P \simeq P_c$, see panel 3 in Fig. 6B. This process is thermally activated since the vortex diameter strongly increases as $T \rightarrow T_c$. However, at $f \simeq f_d$ and in the temperature region where vortices become depinned, the LO effect reduces the vortex core ending up in only a small variation in the vortex core size during periodically driven motion. This reduces the probability of the overlap between normal regions and, therefore, the avalanche is triggered at higher microwave powers for a given temperature (Lara et al., 2017).

Future directions

Superconductivity in curved 3D nanoarchitectures

3D nanoarchitectures have become of increasing importance across various domains of science and technology (Fomin, 2018; Fomin, 2021; Makarov et al., 2022), including magnetism (Fernández-Pacheco et al., 2017; Skjærvø et al., 2020), photonics (von Freymann et al., 2010), magnonics (Gubbiotti, 2019) and plasmonics (Winkler et al., 2017). From the applications viewpoint, the extension of nanoscale superconductors into the third dimension allows for the full-vector-field sensing in quantum interferometry (Martínez-Pérez et al., 2018), noise-equivalent power reduction in bolometry (Lösch et al., 2019) and reduction of footprints of fluxonic devices (Fourie et al., 2011). Extending quasi-1D or -2D superconductor manifolds into the third dimension allows for their thermal decoupling from the substrate and the development of multi-terminal devices and circuits with complex interconnectivity. Herewith, curved geometries bring about the smoothness of conjunctions, which allows for avoiding undesired weak links at sharp turns (Porriati et al., 2019) and minimizing current-crowding effects (Clem and Berggren, 2011). The complex interplay between Meissner screening currents, Abrikosov vortices and slips of the phase of the superconducting order parameter in curved 3D nanoarchitectures gives rise to topological modes which do not occur in planar 2D films (Fomin and Dobrovolskiy, 2022). Nowadays, topological transitions between the different regimes in the vortex and phase-slip dynamics in curved 3D nanoarchitectures are a subject of extensive investigations (Córdoba et al., 2019; Fomin et al., 2022; Fomin et al., 2012; Fomin et al., 2020). The stability of these regimes under intense dc transport currents and high ac frequencies requires experimental and theoretical exploration.

Cryogenic magnonics and magnon fluxonics

The interplay between the fundamental excitations in superconducting and magnetic systems has recently given birth to the research domains of cryogenic magnonics and magnon fluxonics (Dobrovolskiy and Chumak, 2022; Dobrovolskiy et al., 2019c; Golovchanskiy et al., 2019; Golovchanskiy et al., 2018). Magnonics is one of the most rapidly growing research fields in modern magnetism (Barman et al., 2021). It is concerned with the dynamics of spin waves (and their quanta—magnons), which are precessional excitations of ordered spins in magnetic materials, and their use for wave-based information processing (Chumak et al., 2022). In this regard, Meissner screening currents offer interesting possibilities to control the magnetization dynamics in superconductor-based hybrids at low temperatures (Golovchanskiy et al., 2019; Golovchanskiy et al., 2018). Furthermore, the periodic modulation of the local magnetic field emanating from the vortex cores induces Bloch-like bandgaps in the magnon frequency spectrum while a current-driven vortex lattice acts as a moving Bragg grating (Barnes et al., 1996), leading to Doppler shifts of the magnon bandgap frequencies (Dobrovolskiy and Chumak, 2022; Dobrovolskiy et al., 2019c).

The fast motion of the vortex lattice opens up new prospects for the magnon-fluxon interaction: the phenomenon of Cherenkov radiation of magnons (Bespalov et al., 2014; Bulaevskii et al., 2005; Shekhter et al., 2011), when the vortex lattice velocity reaches the phase velocity of the spin wave. The experimentally observed magnon emission is unidirectional (spin wave propagates in the direction of motion of the vortex lattice), monochromatic (magnon wavelength is equal to the vortex lattice parameter), and coherent (spin-wave phase is self-locked due to quantum interference with eddy currents in the superconductor) (Dobrovolskiy et al., 2021). The magnon radiation is accompanied by a magnon Shapiro step in the I - V curve of the superconductor, reduces the dissipation (Bespalov et al., 2014; Bulaevskii et al., 2005; Shekhter et al., 2011), and inhibits the FFI onset (Dobrovolskiy et al., 2021). Thus, the generation of collective modes by a fast-moving vortex lattice can be viewed as an interesting approach for the inhibition of FFI and studies of fast vortex dynamics. Further research should address magnetic flux transport mechanisms in transient Abrikosov-Josephson vortex regimes (Embon et al., 2017) and ultra-fast vortex motion in systems exhibiting a superconductor-insulator transition (Porri et al., 2022).

Conclusion

Summing up, the exploration of ultrafast vortex dynamics in superconductors has recently turned into a major research avenue. These studies are motivated by the enhancement of current-carrying capacity of superconductors, reduction of microwave loss therein, and improvement of superconducting single-photon detectors. From the viewpoint of basic research, the fast-moving ensemble of quantized magnetic flux lines entails emerging nonequilibrium phenomena and complex interactions, and it allows for the generation of collective modes in superconductor-based systems. It is anticipated that in the years to come, research along these lines will fuel the domain of vortex matter under nonequilibrium conditions and will lead to the development of novel applications.

Abstract

Anyons are particles obeying statistics of neither bosons nor fermions. Non-Abelian anyons, whose exchanges are described by a non-Abelian group acting on a set of wave functions, are attracting a great attention because of possible applications to topological quantum computations. Braiding of non-Abelian anyons corresponds to quantum computations. The simplest non-Abelian anyons are Ising anyons which can be realized by Majorana fermions hosted by vortices or edges of topological superconductors, $\nu = 5/2$ quantum Hall states, spin liquids, and dense quark matter. While Ising anyons are insufficient for universal quantum computations, Fibonacci anyons present in $\nu = 12/5$ quantum Hall states can be used for universal quantum computations. Yang-Lee anyons are nonunitary counterparts of Fibonacci anyons. Another possibility of non-Abelian anyons (of bosonic origin) is given by vortex anyons, which are constructed from non-Abelian vortices supported by a non-Abelian first homotopy group, relevant for certain nematic liquid crystals, superfluid ^3He , spinor Bose-Einstein condensates, and high density quark matter. Finally, there is a unique system admitting two types of non-Abelian anyons, Majorana fermions (Ising anyons) and non-Abelian vortex anyons. That is $^3\text{P}_2$ superfluids (spin-triplet, p -wave pairing of neutrons), expected to exist in neutron star interiors as the largest topological quantum matter in our universe.

Key points

- Unlike fermions and bosons, the exchange of non-Abelian anyons is described by unitary transformations that operate on topologically protected degenerate ground states. The adiabatic exchanges of two or more non-Abelian anyons manipulate quantum information stored in a set of degenerate ground states, leading to topological quantum computations.
- The simplest non-Abelian anyons are Ising anyons which are predicted to exist as Majorana zero modes in topological superconductors, fractional quantum Hall states, Kitaev materials, and dense quark matter.
- Another non-Abelian anyons are vortex anyons, which are constructed from non-Abelian vortices supported by a non-Abelian first homotopy group. Such vortex anyons exist in liquid crystals, superfluid ^3He , spinor Bose-Einstein condensates, and high-density quark matter.
- $^3\text{P}_2$ superfluids, which are expected to be realized in neutron stars, provide unique systems simultaneously admitting two kinds of non-Abelian anyons, that is, Ising anyons and vortex anyons.

Introduction

In three spatial dimensions, all particles are either bosons or fermions in quantum physics, that is, a wave function of multiparticle states is symmetric (antisymmetric) under the exchanges of two bosons (fermions). On contrary, in two spatial dimensions, there exist exotic particles classified to neither bosons nor fermions, *anyons*. A wave function of two anyons receives a nontrivial phase factor under their exchanges (Leinaas and Myrheim, 1977; Wilczek, 1982). Such exotic particles play essential roles in fractional quantum Hall states (Halperin, 1984; Arovas et al., 1984), and have been experimentally observed for $\nu = 1/3$ fractional quantum Hall states (Bartolomei et al., 2020; Nakamura et al., 2020).

Recently, yet exotic particles attracted great attention, that is, *non-Abelian anyons*. Non-Abelian anyons are described by a set of multiple wave functions, and the exchanges of two non-Abelian anyons lead to unitary matrix operations on a set of wave functions. They have been theoretically predicted to exist in $\nu = 5/2$ fractional quantum Hall states (Moore and Read, 1991; Nayak and Wilczek, 1996), topological superconductors (SCs) and superfluids (SFs) (Read and Green, 2000; Ivanov, 2001; Kitaev, 2001), and spin liquids (Kitaev, 2006; Motome and Nasu, 2020), and experimental observation is pursued. Non-Abelian anyons are attracting significant interests owing to the possibility to offer a platform of topologically protected quantum computations realized by braiding of non-Abelian anyons (Kitaev, 2003; Kitaev and Laumann, 2008; Nayak et al., 2008; Pachos, 2012; Sarma et al., 2015; Field and Simula, 2018). Since the Hilbert space and braiding operations are topologically protected, they are robust against noises in contrast to the conventional quantum computation methods. Recently, it has been reported that non-Abelian braiding and fusions have been experimentally realized in a superconducting quantum processor, where the fusion and braiding protocols are implemented using a quantum circuit on a superconducting quantum processor (Andersen et al., 2022), thereby opening a significant step to realize topological quantum computations.

One of the main routes to realize non-Abelian anyons is based on Majorana fermions in topological SCs (Ivanov, 2001; Kitaev, 2001; Alicea, 2012; Leijnse and Flensberg, 2012; Beenakker, 2013; Silaev and Volovik, 2014; Elliott and Franz, 2015; Sato and

Fujimoto, 2016; Mizushima et al., 2016; Sato and Ando, 2017; Beenakker, 2020; Marra, 2022). Majorana fermions were originally proposed in high energy physics to explain neutrinos; they are particles that coincide with their own antiparticles (Majorana, 1937). In condensed matter physics, Majorana fermions are localized at vortices or edge of materials for which several protocols of non-Abelian braiding were proposed. Non-Abelian anyons constructed from Majorana fermions are so-called Ising anyons. They are not enough for universal quantum computations, and thus some nontopological process should be included (Nayak et al., 2008). In contrast, another type of anyons called Fibonacci anyons (Trebst et al., 2008) can offer a promising platform for universal topological quantum computation that all quantum gates are implemented by braiding manipulation in a topologically protected way (Preskill, 2004; Bonesteel et al., 2005; Hormozi et al., 2007). Such Fibonacci anyons are proposed to exist in $\nu = 12/5$ quantum Hall states, a junction made of a conventional SC and a $\nu = 2/3$ fractional quantum Hall state (Mong et al., 2014), interacting Majorana fermions realized in a septuple-layer structure of topological SCs (Hu and Kane, 2018), and Rydberg atoms in a lattice (Lesanovsky and Katsura, 2012). Yang-Lee anyons are also proposed as nonunitary counterparts of Fibonacci anyons, obeying nonunitary non-Abelian statistics (Ardonne et al., 2011; Freedman et al., 2012; Sanno et al., 2022).

The aforementioned anyons are all quasiparticle excitations composed of fermions. On the other hand, a different type of non-Abelian anyons can be composed of bosons in certain ordered states accompanied with symmetry breakings $G \rightarrow H$. They are called non-Abelian vortex anyons, whose exchange statistics are non-Abelian due to non-Abelian vortices, that is quantum vortices supported by a non-Abelian first homotopy (fundamental) group of order parameter manifolds, $\pi_1(G/H)$ (Bais, 1980; Wilczek and Wu, 1990; Bucher, 1991; Brekke et al., 1993; Lo and Preskill, 1993; Lee, 1994; Brekke et al., 1997).¹ Such non-Abelian vortices exist in liquid crystals (Poenaru and Toulouse, 1977; Volovik and Mineev, 1977; Mermin, 1979; Lavrentovich and Kleman, 2001), ³He SFs (Balachandran et al., 1984; Salomaa and Volovik, 1987; Volovik, 2003), spinor Bose-Einstein condensates (BECs) (Semenoff and Zhou, 2007; Kobayashi et al., 2009, 2012; Borgh and Ruostekoski, 2016), and high-density quark (QCD) matter (Fujimoto and Nitta, 2021a, b, c; Eto and Nitta, 2021). Non-Abelian braiding of vortex anyons in spinor BECs and its application to quantum computations were proposed (Mawson et al., 2019).

In addition to these systems admitting one type of non-Abelian anyons, there is the unique system simultaneously admitting two kinds of non-Abelian anyons, Ising anyons based on Majorana fermions and non-Abelian vortex anyons. It is a ³P₂ SF, spin-triplet and *p*-wave pairing with the total angular momentum two (Hoffberg et al., 1970; Tamagaki, 1970; Takatsuka and Tamagaki, 1971; Takatsuka, 1972; Richardson, 1972). Such ³P₂ SFs are expected to be realized by neutrons, relevant for neutron star interiors (Sedrakian and Clark, 2018). ³P₂ SFs are the largest topological SFs in our universe (Mizushima et al., 2017) and admit non-Abelian vortices (Masuda and Nitta, 2020). Non-Abelian vortices host Majorana fermions in their cores (Masaki et al., 2022), thus behaving as non-Abelian anyons.

The purpose of this article is to summarize these non-Abelian anyons of various types. After introducing basics of non-Abelian anyons in Section “Non-Abelian anyons,” we describe non-Abelian anyons in fermionic and bosonic systems, based on Majorana fermions and non-Abelian first homotopy group in Sections “Non-Abelian anyons in topological SCs” and “Non-Abelian vortex anyons,” respectively. In Section “³P₂ Topological SFs,” we introduce ³P₂ SFs as the unique system simultaneously admitting two kinds of non-Abelian anyons. We summarize this article in Section “Summary.”

Non-Abelian anyons

Braid group and quantum statistics

Here we consider pointlike topological defects (e.g., vortices in two-dimensional *spinless* SCs), which behave as identical particles in a two-dimensional plane. The exchange of *n* particles in three or higher dimension is described by the symmetric group S_n (Leinaas and Myrheim, 1977). There are two one-dimensional representations of S_n , ± 1 , due to even or odd permutation and $+1$ (-1) corresponds the Bose (Fermi) statistics. Two dimension is special and the exchange of particles is given by the braid group B_n (Wu, 1984). The braid of particles is expressed as a set of operators T_k ($1 \leq k \leq n-1$) that exchange the neighboring *k*th and (*k* + 1)th particles in an anticlockwise direction. The operators obey the relations (see Fig. 1)

$$T_i T_j T_i = T_j T_i T_j, \quad \text{for } |i-j| = 1, \quad (1)$$

$$T_i T_j = T_j T_i, \quad \text{for } |i-j| \geq 2. \quad (2)$$

The exotic statistics of particles represented by the braid group stems from the relation $T_i^{-1} \neq T_i$. In the one-dimensional representation, the generator of T_i is given by a phase factor that a wave function under the exchange of particles acquires, $\tau_j \equiv \tau(T_j) = e^{i\theta_j}$ ($0 \leq \theta_j < 2\pi$). The relation in Eq. (1) implies that the exchange operation of any two particles induces the same phase factor $\tau_1 = \tau_2 = \dots = \tau_{n-1} = e^{i\theta}$. The phase factor characterizes the quantum statistics of particles (Wu, 1984), and the absence of the relation $T_i^2 = 1$ allows for the fractional (anyon) statistics with neither $\theta = 0$ (bosons) nor $\theta = \pi$ (fermions). In addition to the one-dimensional representation, the braid group has non-Abelian representations. In Section “Non-Abelian anyons in topological

¹The term “non-Abelian” on vortices depends on the context. In the other contexts (in particular in high energy physics), vortices in a symmetry breaking $G \rightarrow H$ with non-Abelian magnetic fluxes are often called non-Abelian even though $\pi_1(G/H)$ the first homotopy group is Abelian (Hanany and Tong, 2003; Auzzi et al., 2003; Eto et al., 2006; Shifman and Yung, 2007; Eto et al., 2014). In condensed matter physics, vortices with Majorana fermions in their cores are also sometimes called non-Abelian vortices (because they are non-Abelian anyons). In this article, the term “non-Abelian” on vortices is used only for vortices with non-Abelian first homotopy group π_1 .

Fig. 1 Schematic of the braid relations in Eqs. (1) and (2): $T_i T_j = T_j T_i$ for $|i - j| \geq 2$ (left) and $T_i T_{i+1} T_i = T_{i+1} T_i T_{i+1}$ for $|i - j| = 1$ (right).

SCs," we will show that the generators of the braid of Majorana zero modes are noncommutative as $[\tau_i, \tau_j] \neq 0$ for $|i - j| = 1$ and the pointlike defects hosting Majorana modes behave as non-Abelian anyons.

Although the braid group is trivial in three dimensions, a three-dimensional model with pointlike topological defects, which host Majorana modes and obey the non-Abelian statistics, has been proposed (Teo and Kane, 2010a). The non-Abelian statistics of the defects, which behave as hedgehogs, can be interpreted as the projective ribbon permutation statistics (Freedman et al., 2011b, a). Such non-Abelian statistics enables to construct three-dimensional networks of topological superconducting wires supporting Majorana modes.

Non-Abelian anyons

In three spatial dimensions, the statistics of particles is determined by their intrinsic spins. According to the spin statistics theorem, all particles with integer (half-integer) spin are bosons (fermions). A pair formed by two fermions with the spin $1/2$ behaves as a boson, and the spin of the composite particle obeys the "fusion rule" $\frac{1}{2} \otimes \frac{1}{2} = 0 \oplus 1$, where 0 and 1 denote the spin singlet and triplet states, respectively. When particles are trapped in a two-dimensional plane, however, there is another possibility that is neither fermions nor bosons, that is, anyons. In general, anyons can be characterized by the topological charge, the fusion rule (N_{ab}^c), the associative law (the F -matrix), and the braiding operation (the R -matrix) (Preskill, 2004; Nayak et al., 2008; Pachos, 2012).

Let 1 and $\{a, b, \dots\}$ be the vacuum and the different species of particles, respectively. Consider the anyon model spanned by $M = \{1, a, b, \dots\}$ and bring two anyons a and b together. The fused particle also belongs to M . The fusion rule is represented by

$$a \otimes b = \sum_{c \in M} N_{ab}^c c, \quad (3)$$

where fusion coefficients N_{ab}^c are nonnegative integers. Fig. 2A shows the diagrammatic expression of the fusion of two anyons with topological charges a and b to an anyon with charge c . When N_{ab}^c is not zero for only one value of c , the fusion of paired a and b anyons is uniquely determined and the anyon is called the Abelian anyon. The non-Abelian anyons are characterized by two or more coefficients that satisfy $N_{ab}^c \neq 0$. In the context of quantum computation, the fusion rule determines the Hilbert space that encodes quantum information, and quantum computation is implemented by the braiding manipulation of non-Abelian anyons in a topologically protected way. Fig. 2B shows the diagrammatic expression of the R -matrix. When one anyon moves around the other, the pairwise anyons acquire a phase. As mentioned below, the R -matrix describes a phase resulting from the exchange of anyons a and b which fuse to an anyon c . Let us also consider the fusion of three anyons a , b , and c into an anyon d . The outcome of

Fig. 2 (A) Diagram of the fusion of two anyons a and b to an anyon c . Diagrammatic expressions of the R -matrix (B) and the F -matrix (C).

the fusion process is independent of order in which the anyons are to be fused. This implies that the fusion process obeys the associative law, $(a \otimes b) \otimes c = a \otimes (b \otimes c)$, which is characterized by the F -matrix. The F matrix represents the transformation between different fusion bases or the choice of order of fusion, which is expressed as shown in Fig. 2C. The R -matrix and the F -matrix are the building blocks for constructing the braid group in multiple anyon systems (Preskill, 2004).

Ising anyons

An example of the non-Abelian anyons is the Ising anyon (Kitaev, 2006; Nayak et al., 2008; Pachos, 2012). The Ising anyon model consists of the vacuum 1 , Ising anyons σ , and Dirac (complex) fermions ψ , which obey the fusion rules

$$\sigma \otimes \sigma = 1 \oplus \psi, \quad \sigma \otimes \psi = \sigma, \quad \psi \otimes \psi = 1, \quad 1 \otimes x = x, \quad (4)$$

where $x \in \{1, \sigma, \psi\}$. Consider three Ising anyons, where the two left-most anyons fuse into either 1 or ψ (see Fig. 2C with $(a, b, c) \rightarrow \sigma$ and $i, j = \{1, \psi\}$). The R -matrix and the F -matrix are given, respectively, by

$$R = \begin{pmatrix} R_1^{\sigma\sigma} & 0 \\ 0 & R_\psi^{\sigma\sigma} \end{pmatrix} = e^{-i\pi/8} \begin{pmatrix} 1 & 0 \\ 0 & i \end{pmatrix}, \quad (5)$$

$$F_{\sigma\sigma\sigma}^\sigma = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}. \quad (6)$$

The diagonal components of the R -matrix are the phases resulting from the counterclockwise exchange of two left-most Ising anyons (σ) fusing to 1 or ψ while the twice exchange operation of two right-most Ising anyons is represented by the unitary matrix, $F^{-1}R^2F = e^{-i\pi/4}\sigma_x$. Hence, braiding two anyons corresponds to the implementation of the quantum gates acting on the quantum states spanned by 1 and ψ .

In general, the anyons are described by conformal field theory, corresponding to gapless edge states residing in the boundary of two-dimensional gapped topological phases. For Ising anyons, the theory is the conformal field theory with the central charge $c = 1/2$, which describes critical Ising models such as the two-dimensional Ising model at the point of second-order phase transition (Di Francesco et al., 1997).

The Moore-Read state in the fractional quantum Hall state at the filling factor $\nu = 5/2$ supports this type of non-Abelian anyons (Nayak et al., 2008). The Ising anyons can also be realized in the Kitaev's honeycomb model, which is an exactly solvable model of quantum spin liquid states (Kitaev, 2006). In this model, the spins are fractionalized to Majorana fermions coupled to $\mathbb{Z}_2$ gauge fields. The Ising anyons appear as Majorana zero modes bound to the $\mathbb{Z}_2$ flux. Materials including $4d$ or $5d$ atoms with a strong spin-orbit coupling have been proposed as candidates of Kitaev magnets, and the half-integer thermal Hall effect was reported in α -RuCl₃ (Kasahara et al., 2018; Yamashita et al., 2020; Yokoi et al., 2021; Bruin et al., 2022), which is a signature of Majorana fermions in the chiral quantum spin liquid phase (Vinkler-Aviv and Rosch, 2018; Ye et al., 2018). Apart from materials, Google team reported the demonstration of fusion and braiding rules of non-Abelian Ising anyons on a superconducting quantum processor, where the fusion and braiding protocols are implemented using a quantum circuit on a superconducting quantum processor (Andersen et al., 2022). Another platform to realize Ising anyons is a topological SC. In the context of topological SCs, the Ising anyons (σ) appear as Majorana zero modes bound at their boundaries or topological defects, such as the surface, interface, and vortices (Read and Green, 2000; Kitaev, 2001; Nayak et al., 2008; Alicea, 2012; Sato and Fujimoto, 2016; Mizushima et al., 2016). Pairwise Majorana zero modes form a complex fermion that can define either the unoccupied state (1) or the occupied state (ψ) of the zero energy eigenstate, implying $\sigma \otimes \sigma = 1 \oplus \psi$. The vacuum 1 corresponds to a condensate of Cooper pairs, while ψ represents a Bogoliubov quasiparticle which can pair into a condensate, that is, $\psi \otimes \psi = 1$. The detailed properties and realization of Majorana zero modes in topological SCs are described in Sections "Majorana zero modes as Ising anyons" and "Platforms for Majorana zero modes."

Fibonacci anyons

Another example is the Fibonacci anyons (Trebst et al., 2008). The Fibonacci anyon model consists of the vacuum 1 and the nontrivial anyon τ , which obey the fusion rules

$$\tau \otimes \tau = 1 \oplus \tau, \quad 1 \otimes x = x, \quad (7)$$

where $x = 1, \tau$. The first rule implies that the fusion of two anyons may result in either annihilation or creation of a new anyon, and thus the Fibonacci anyon may be its own antiparticle. Repeated fusions of the $n + 1$ τ -anyons result in either the vacuum or the τ anyon as $\tau \otimes \tau \otimes \dots \otimes \tau = a_n \cdot 1 \oplus b_n \tau$, where $a_n = 1$ for $n = 2$ and $a_n = n - 2$ for $n \geq 3$. The coefficient b_n grows as the Fibonacci series, and the first few values in the sequence are $b_2 = 1, b_3 = 2, b_4 = 3, b_5 = 5, \dots$. The R -matrix and the F -matrix are given, respectively, by

$$R = \begin{pmatrix} R_1^{\tau\tau} & 0 \\ 0 & R_\tau^{\tau\tau} \end{pmatrix} = \begin{pmatrix} e^{i4\pi/5} & 0 \\ 0 & -e^{i2\pi/5} \end{pmatrix}, \quad (8)$$

$$F_{\tau\tau\tau}^{\tau} = \begin{pmatrix} \phi^{-1} & \phi^{-1/2} \\ \phi^{-1/2} & -\phi^{-1} \end{pmatrix} \quad (9)$$

where $\phi = (1 + \sqrt{5})/2$ is the golden ratio. The Fibonacci anyons are described by the level-1 G_2 Wess–Zumino–Witten theory with the central charge $c = 14/5$ (Mong et al., 2014), where G_2 is the simplest exceptional Lie group. While Ising anyons are not sufficient for universal quantum computation, the Fibonacci anyon systems can offer a promising platform for universal topological quantum computation that all quantum gates are implemented by braiding manipulation in a topologically protected way (Preskill, 2004; Bonesteel et al., 2005; Hormozi et al., 2007).

The existence of the Fibonacci anyons is predicted in the $\nu = 12/5$ fractional quantum Hall state that is described by the Read–Rezayi state (Read and Rezayi, 1999). It is also proposed that a junction made of a conventional SC and the $\nu = 2/3$ fractional quantum Hall state supports the Fibonacci anyons (Mong et al., 2014). Fibonacci anyons can also be made from interacting Majorana fermions realized in a septuple-layer structure of topological SCs (Hu and Kane, 2018) and from Rydberg atoms in a lattice (Lesanovsky and Katsura, 2012).

Yang-Lee anyons

There are nonunitary counterparts of Fibonacci anyons, which are referred to as Yang-Lee anyons. The conformal field theory corresponding to Yang-Lee anyons is nonunitary and Galois conjugate to the Fibonacci conformal field theory (Ardonne et al., 2011; Freedman et al., 2012). Because of nonunitarity, the central charge and the scaling dimension for the one nontrivial primary field are negative, $c = -22/5$ and $\Delta = -2/5$, respectively. As shown in Eq. (9), the F -matrix for Fibonacci anyons is given by the golden ratio ϕ , that is, one solution of the equation $x^2 = 1 + x$, which is an algebraic analog of the fusion rule. The F -matrix for Yang-Lee anyons is obtained from Eq. (9) by replacing $\phi \rightarrow -1/\phi$ as

$$F_{\tau\tau\tau}^{\tau} = \begin{pmatrix} -\phi & i\sqrt{\phi} \\ i\sqrt{\phi} & \phi \end{pmatrix}, \quad (10)$$

as $-1/\phi$ is the other solution of the equation $x^2 = 1 + x$. In Eq. (10), the bases of the F -matrix are spanned by the vacuum state 1 and a Yang-Lee anyon τ . The R -matrix are given by

$$R = \begin{pmatrix} R_1^{\tau\tau} & 0 \\ 0 & R_{\tau}^{\tau\tau} \end{pmatrix} = \begin{pmatrix} e^{i2\pi/5} & 0 \\ 0 & e^{i\pi/5} \end{pmatrix}. \quad (11)$$

Unlike the Fibonacci anyons, braiding two Yang-Lee anyons is represented by a combination of the R -matrix and the nonunitary matrix, $F^{-1}RF$. While Yang-Lee anyons obey the same fusion rule as that of Fibonacci anyons given by Eq. (7), the F -matrix in Eq. (10) is the nonunitary and the Yang-Lee anyons obey the nonunitary non-Abelian statistics.

The nonunitary conformal field theory with $c = -22/5$ describes the nonunitary critical phenomenon known as the Yang-Lee edge singularity (Cardy, 1985). Let us consider the Ising model with an imaginary magnetic field ih ($h \in \mathbb{R}$). For temperatures above the critical temperature, the zeros of the partition function in the thermodynamic limit, which are referred to as the Lee–Yang zeros, accumulate on the line $h > h_c$ and the edge of the Lee–Yang zeros corresponds to the critical point h_c (Lee and Yang, 1952). As h ($> h_c$) approaches the edge, the density of zeros has a power-law behavior as $|h - h_c|^\sigma$, which characterizes the critical phenomenon (Kortman and Griffiths, 1971; Fisher, 1978). For instance, the magnetization exhibits singular behavior with the same critical exponent σ . The Yang-Lee edge singularity is also realized by the quantum Ising model with a real transverse field and a pure-imaginary longitudinal field (von Gehlen, 1991).

The quantum Ising model with an imaginary longitudinal field, which supports the Yang-Lee anyons, can be constructed from Majorana zero modes in a network of topological superconducting wires coupled with dissipative electron baths (Sanno et al., 2022). The Majorana modes bound at the end points of one-dimensional topological SCs constitute spin 1/2 operators. A coupling of Majorana zero modes with electrons in a metallic substrate plays a role of the pure-imaginarily longitudinal field, while the tunneling of Majorana zero modes between neighboring superconducting wires induces a transverse magnetic field. Schemes for the fusion, measurement, and braiding of Yang-Lee anyons are also proposed in Sanno et al. (2022). As mentioned above, the Yang-Lee anyons obey the nonunitary non-Abelian statistics. The nonunitary evolution of quantum states has been discussed in connection with measurement-based quantum computation (Terashima and Ueda, 2005; Usher et al., 2017; Piroli and Cirac, 2020; Zheng, 2021). Although the Yang-Lee anyons with the nonunitary F -matrix are not suitable for application to unitary quantum computation, they can be the building blocks for the construction of measurement-based quantum computation. In addition, as the nonunitary quantum gates can be implemented by braiding manipulations, the Yang-Lee anyon systems may offer a quantum simulator for nonunitary time evolution of open quantum systems in a controllable way.

Vortex anyons

In this article, we also discuss non-Abelian anyons made of bosonic (topological) excitations in ordered states. The nontrivial structure of the order parameter manifold appears in the liquid crystals, spin-2 BECs, the A phase of SF ^3He , dense QCD matter, and $^3\text{P}_2$ SFs. The line defects in such ordered systems, such as vortices, are represented by non-Abelian first homotopy group and their topological charges are noncommutative. Such topological defects with noncommutative topological charges behave as

non-Abelian anyons, called the non-Abelian vortex anyons. In Section “Non-Abelian vortex anyons,” we demonstrate that order parameter manifolds in nematic liquid crystals and spin-2 BECs admit the existence of non-Abelian vortices and show the fusion rules of such non-Abelian vortex anyons.

Non-Abelian anyons in topological SCs

Majorana zero modes as Ising anyons

Majorana zero modes

An elementary excitation from superconducting ground states is a Bogoliubov quasiparticle that is a superposition of the electron and hole. The quasiparticle excitations are described by the Bogoliubov-de Gennes (BdG) Hamiltonian

$$H = \sum_{ij} (\psi_i^\dagger, \psi_i) \mathcal{H}_{ij} \begin{pmatrix} \psi_j \\ \psi_j^\dagger \end{pmatrix}, \quad (12)$$

$$\mathcal{H}_{ij} = \begin{pmatrix} h_{ij} & \Delta_{ij} \\ \Delta_{ij}^\dagger & -h_{ij}^* \end{pmatrix}. \quad (13)$$

Here, ψ_j is the N -component vector of the electron field operator and $\mathcal{H}$ is the $2N \times 2N$ Hermitian matrix, where N is the sum of the spin degrees of freedom and the number of the lattice sites and so on. The $N \times N$ Hermitian matrix h describes the normal state Hamiltonian and the superconducting pair potential Δ obeys $\Delta^t = -\Delta$ because of the Fermi statistics, where a^t denotes the transpose of a matrix a . The BdG Hamiltonian naturally holds the particle-hole symmetry

$$\mathcal{C}\mathcal{H}\mathcal{C}^{-1} = -\mathcal{H}, \quad (14)$$

where the particle-hole operator $\mathcal{C} = \Theta K$ is an antiunitary operator composed of the unitary operator Θ and the complex conjugation operator K . The self-conjugate Dirac fermions are called Majorana fermions, where the quantized field $\Psi \equiv (\psi, \psi^\dagger)^t$ obeys

$$\Psi = \mathcal{C}\Psi, \quad \mathcal{C}^2 = +1. \quad (15)$$

We expand the quantized field Ψ in terms of the energy eigenstates. The energy eigenstates are obtained from the BdG equation,

$$\sum_j \mathcal{H}_{ij}(\varphi_E)_j = E(\varphi_E)_i, \quad (16)$$

which describes the quasiparticle with the energy E and the wave function φ_E . Eq. (14) guarantees that the quasiparticle state with $E > 0$ and φ_E is accompanied by the negative energy state with $-E$ and $\varphi_{-E} = \mathcal{C}\varphi_E$. Thus, the negative energy states are redundant as long as the particle-hole symmetry is maintained. Let η_E be the quasiparticle operator which satisfies the anticommutation relations, $\{\eta_E, \eta_{E'}^\dagger\} = \delta_{E,E'}$ and $\{\eta_E, \eta_{E'}\} = \{\eta_E^\dagger, \eta_{E'}^\dagger\} = 0$ ($E, E' > 0$). The self-charge conjugation relation (15) then implies that the quasiparticle annihilation operator with a positive energy is equivalent to the creation with a negative energy as $\eta_E = \eta_{-E}^\dagger$, and Ψ is expanded only in terms of positive energy states as $\Psi(r) = \sum_{E>0} [\varphi_E \eta_E + \mathcal{C}\varphi_E \eta_E^\dagger]$. The condition (15) can be fulfilled by odd-parity SCs. In the absence of spin-orbit coupling, the spin-singlet pair potential is always invariant under the spin rotation, and the particle-hole exchange operator is given by $\mathcal{C}^2 = -1$ in each spin sector. Hence, spin-singlet SCs cannot satisfy Eq. (15). Spin-orbit coupling, however, enables even spin singlet SCs to host Majorana fermions (Sato and Ando, 2017; Alicea, 2012; Sato and Fujimoto, 2016).

Now, let us suppose that a single zero-energy state exists, and φ_0 is its wave function. Then, we can rewrite the quantized field to

$$\Psi = \varphi_0 \gamma + \sum_{E>0} [\varphi_E \eta_E + \mathcal{C}\varphi_E \eta_E^\dagger]. \quad (17)$$

We have introduced γ , instead of $\eta_{E=0}$, to distinguish the zero mode from other energy eigenstates. Owing to Eq. (14), the zero-energy quasiparticle is composed of equal contributions from the particle-like and hole-like components of quasiparticles, that is, $\mathcal{C}\varphi_0 = \varphi_0$. The self-conjugate constraint in Eq. (15) imposes the following relations:

$$\gamma^\dagger = \gamma, \quad (18)$$

and $(\gamma)^2 = 1$ and $\{\gamma, \eta_{E>0}\} = \{\gamma, \eta_{E>0}^\dagger\} = 0$. The quasiparticle obeying this relation is called the Majorana zero mode. The zero energy states appear in a topological defect of topological SCs, such as chiral SCs. In Fig. 3A, we show the spectrum of Andreev bound states bound at a vortex in a chiral SC, where the level spacing between the zero mode and the lowest excitation state is $\Delta E \sim \Delta_0^2/\varepsilon_F$ (Kopnin and Salomaa, 1991; Volovik, 1999; Read and Green, 2000; Matsumoto and Heeb, 2001). In many vortices, the hybridization between neighboring Majorana modes gives rise to the formation of the band structure with the width $\Delta E_M \sim e^{-D/\xi}$ (Cheng et al., 2009; Mizushima and Machida, 2010), where D and ξ are the mean distance of neighboring vortices and superconducting coherence length, respectively (see Fig. 3B).

The Majorana zero modes exhibit the non-Abelian anyonic behaviors (Ivanov, 2001). To clarify this, we start with two Majorana zero modes residing in an SC. Using two Majorana operators, γ^1 and γ^2 , we define the new fermion operators c and $c^\dagger$ as

Fig. 3 Schematic of the quasiparticle states bound at a single vortex (A) and energy spectrum of many vortices (B) in a *spinless* SC, where the level spacing of vortex bound states is $\Delta E \sim \Delta_0^2/\varepsilon_F$ and ΔE_M denotes the band width of Majorana states bound at each core. (C) Operations of the braiding matrices U_{12} and U_{23} and the F -matrix in four Majorana modes.

$$c = \frac{1}{2}(\gamma^1 + i\gamma^2), \quad c^\dagger = \frac{1}{2}(\gamma^1 - i\gamma^2), \quad (19)$$

which obey the anticommutation relations, $\{c, c^\dagger\} = 1$ and $\{c, c\} = \{c^\dagger, c^\dagger\} = 0$. The two degenerate ground states are defined as the vacuum $|0\rangle$ and the occupied state of the zero energy state $|1\rangle = c^\dagger|0\rangle$, respectively, where the former (latter) state is the even (odd) fermion parity. We note that as the BdG Hamiltonian for superconducting states is generally commutable with the parity operator, the fermion parity remains as a good quantum number. For the even (odd) parity sector, the Hilbert space is spanned by using $|0\rangle$ ($|1\rangle$) and excited states that are constructed as $\eta_E^\dagger \eta_E^\dagger \eta_E^\dagger \cdots |0\rangle$ ($\eta_E^\dagger \eta_E^\dagger \eta_E^\dagger \cdots |1\rangle$). The Majorana operators, γ^1 , γ^2 , and $i\gamma^1\gamma^2$, act on the Hilbert space as the Pauli matrices σ_x , σ_y , and σ_z , respectively. The eigenstates of the Majorana operators γ^1 and γ^2 are given by the superposition of the degenerate states with different fermion parity, $|0\rangle$ and $|1\rangle$. Hence, the eigenstate of a single Majorana zero mode cannot be a physical state.

Consider $2N$ Majorana zero modes denoted by γ^j ($j = 1, \dots, 2N$), where N complex fermions are constructed by the fusion of i th and j th Majorana zero modes as $c_{ij} = (\gamma^i + i\gamma^j)/2$. We define the occupation number operator of the complex fermion,

$$n_{ij} \equiv c_{ij}^\dagger c_{ij} = \frac{1}{2}(1 + i\gamma^i\gamma^j). \quad (20)$$

In a basis that diagonalizes paired Majorana modes $i\gamma^i\gamma^j$, two eigenvalues of the complex fermion, $n_{ij} = 0$ and 1 , correspond to the fusion channels 1 and ψ , respectively. Hence, the Majorana zero mode is referred to as the Ising anyon. 2^N degenerate ground states are expressed in terms of the occupation numbers as $|n_{12}, n_{34}, \dots\rangle$, which are separated to the sectors of the even/odd fermion parity. Here we assume that the temperature of the system is much lower than the level spacing (ΔE) between the Majorana zero mode and the lowest excitation (non-Majorana) state. Then, the 2^{N-1} degenerate ground states in each fermion parity sector can be utilized as topological qubits, where quantum information is stored in a topologically protected way.

Braiding Majorana zero modes

Here we discuss the braiding statistics of Majorana zero modes γ^i and γ^j and show the non-Abelian statistics of Majorana zero modes (Ivanov, 2001; Alicea et al., 2011; Clarke et al., 2011). While we consider the exchange of Majorana zero modes residing in vortices, the theory is also applicable to Majorana zero modes bound at the end points of one-dimensional topological SCs.

Let T_{ij} be the braid operators that satisfy Eqs. (1) and (2) and transform γ^i and γ^j to $e^{i\theta_i}\gamma^i$ and $e^{i\theta_j}\gamma^j$, respectively. The unitary time evolution of Majorana zero modes is governed by the Heisenberg equation, $i\frac{d}{dt}\gamma^j(t) = [\gamma^j(t), \mathcal{H}(t)]$. The positions of two Majorana modes are adiabatically exchanged in the time interval $[0, T]$. The adiabatic condition defines the lower bound for the time scale of the braiding operation, T , so that T is much longer than the inverse of the level spacing between the Majorana zero mode and the lowest excitation (non-Majorana) state, ΔE . In addition, the upper bound is associated with the band width of Majorana modes $\Delta E_M \sim e^{-D/\xi}$ (see Fig. 3B), that is, $\Delta E^{-1} \ll T \ll \Delta E_M^{-1}$. Within the adiabatic condition, the braiding dynamics of Majorana zero modes can be regarded as the unitary time evolution, $\gamma^j(t) = U_{ij}^\dagger(t)\gamma^j(0)U_{ij}(t)$. After the braiding operation, γ^i (γ^j) changes to γ^j (γ^i) with an additional phase shift. Then, the braiding operation is represented by

$$U_{ij}^\dagger \gamma^i U_{ij} = e^{i\theta_i} \gamma^j, \quad U_{ij}^\dagger \gamma^j U_{ij} = e^{i\theta_j} \gamma^i, \quad (21)$$

where $U_{ij} \equiv U_{ij}(T)$ is the unitary operator which describes the exchange operation of two Majorana zero modes γ^i and γ^j , that is, the representation of T_{ij} . According to the conditions, $(e^{i\theta_i}\gamma^j)^2 = (U_{ij}^\dagger \gamma^j U_{ij})^2 = 1$ and $(\gamma^j)^2 = 1$, the phase shifts obey $\theta_i = n\pi$ and $\theta_j = m\pi$,

where $n, m \in \mathbb{Z}$. The braiding operations must not change the parity of the occupation number defined in Eq. (20) and thus satisfy $U_{ij}^\dagger n_{ij} U_{ij} = n_{ij}$, which imposes the condition, $\theta_1 + \theta_2 = (2n + 1)\pi$, on the phase shift. As a result, the exchange operation of two Majorana zero modes obtains the following braiding rules:

$$U_{ij}^\dagger \gamma^i U_{ij} = \gamma^j, \quad U_{ij}^\dagger \gamma^j U_{ij} = -\gamma^i. \quad (22)$$

Consider four Majorana zero modes denoted by $\gamma^1, \gamma^2, \gamma^3$, and γ^4 , which form two complex fermions as $c_{12} \equiv (\gamma^1 + i\gamma^2)/\sqrt{2}$ and $c_{34} \equiv (\gamma^3 + i\gamma^4)/\sqrt{2}$ (Fig. 3C). When the Majorana mode “3” adiabatically encircles the Majorana mode “2,” both Majorana modes operators acquire the π phase shift, $\gamma^2 \mapsto -\gamma^2$ and $\gamma^3 \mapsto -\gamma^3$, corresponding to the twice operation of Eq. (22). Therefore, the braiding operation changes the occupation numbers of the complex fermion $n_{12} \equiv c_{12}^\dagger c_{12}$ and $n_{34} \equiv c_{34}^\dagger c_{34}$. For example, the above braiding generates a pair of the complex fermions $|11\rangle$ from their vacuum $|00\rangle$. Here these two states are orthogonal, $\langle 11|00\rangle = 0$. The braiding rule can be generalized to $2N$ Majorana modes. The $2N$ Majorana modes are fused to N complex fermions, leading to the 2^{N-1} -fold degeneracy of ground states while preserving fermion parity. As discussed above, when the i th and j th Majorana modes are exchanged with each other, their operators behave as $\gamma_i \mapsto \gamma_j$ and $\gamma_j \mapsto -\gamma_i$. The representation of the braid operator T_{ij} that satisfies Eq. (22) is given in terms of the zero mode operators as (Ivanov, 2001)

$$U_{ij} = e^{i\theta} \exp\left(\frac{\pi}{4} \gamma_j \gamma_i\right) = e^{i\theta} \frac{1}{\sqrt{2}} \left(1 + \gamma_j \gamma_i\right). \quad (23)$$

From now on, we omit the overall Abelian phase factor $e^{i\theta}$ as it is not important for quantum computation. Eq. (23) also holds in the case of the Moore-Read state (Nayak and Wilczek, 1996). For $N = 1$, there is only a single ground state in each sector with definite fermion parity, and the exchange of two vortices results in the global phase of the ground state by $e^{i\pi/4}$. One can easily find that for $N \geq 2$, the exchange operators U_{ij} and U_{jk} do not commute to each other, $[U_{ij}, U_{jk}] \neq 0$, implying the non-Abelian anyon statistics of the Majorana zero modes.

For four Majorana zero modes ($N = 2$), twofold degenerate ground states exist in each fermion-parity sector: $|00\rangle \equiv |\text{vac}\rangle$ and $|11\rangle = c_{12}^\dagger c_{34}^\dagger |\text{vac}\rangle$ in the sector of even fermion parity, and $|10\rangle = c_{12}^\dagger |\text{vac}\rangle$ and $|01\rangle = c_{34}^\dagger |\text{vac}\rangle$ in the sector of odd fermion parity. For the even-parity sector, the representation matrix for the exchange of $1 \leftrightarrow 2$ and $3 \leftrightarrow 4$ (Fig. 3C) is given by

$$U_{12} = U_{34} = e^{-i\frac{\pi}{4}} |00\rangle\langle 00| + e^{i\frac{\pi}{4}} |11\rangle\langle 11|. \quad (24)$$

This merely rotates the phase of the ground state as in the $N = 1$ case. In contrast, the representation matrix for the intervortex exchange ($2 \leftrightarrow 3$ in Fig. 3C) has the mixing terms of the two degenerate ground states $|00\rangle$ and $|11\rangle$,

$$U_{23} = \frac{1}{\sqrt{2}} [|00\rangle\langle 00| - i|00\rangle\langle 11| + |11\rangle\langle 11| - i|11\rangle\langle 00|]. \quad (25)$$

We note that the choice of the pairing to form the complex fermion is arbitrary. The change of the fused Majorana modes corresponds to the change of the basis from one which diagonalizes $i\gamma^1\gamma^2$ and $i\gamma^3\gamma^4$ to another which diagonalizes $i\gamma^1\gamma^3$ and $i\gamma^2\gamma^4$. The basis transformation is represented by the F -matrix as

$$F = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}. \quad (26)$$

The braiding matrix in Eq. (24) implies that the exchange of two Majorana zero modes fusing to ψ ($|11\rangle$) acquires an additional $\pi/2$ phase compared to the fusion channel to 1 ($|00\rangle$). Hence, Eq. (24) satisfies the property of the R -matrix in Eq. (5), that is, $R_1^{\sigma\sigma} = -iR_\psi^{\sigma\sigma}$.

Platforms for Majorana zero modes

The realization of non-Abelian anyons requires to freeze out the internal degrees of freedom of Majorana modes. The simplest example is *spinless* p -wave SCs/SFs, which emerge from the low-energy part of spinful chiral p -wave SCs. To clarify this, we start with spin-triplet SCs, whose pair potential is given by a 2×2 spin matrix (Leggett, 1975)

$$\hat{\Delta}(\mathbf{k}) = \begin{pmatrix} \Delta_{\uparrow\uparrow}(\mathbf{k}) & \Delta_{\uparrow\downarrow}(\mathbf{k}) \\ \Delta_{\downarrow\uparrow}(\mathbf{k}) & \Delta_{\downarrow\downarrow}(\mathbf{k}) \end{pmatrix} = i\sigma_\mu \sigma_\gamma d_\mu(\mathbf{k}) = i\sigma_\mu \sigma_\gamma A_{\mu i} \hat{k}_i, \quad (27)$$

where $\hat{k}_i \equiv k_i/k_F$ is scaled with the Fermi momentum k_F , and the repeated Greek/Roman indices imply the sum over x, y, z . Here we omit the spin-singlet component. Owing to the Fermi statistics, the spin-triplet order parameter, $\mathbf{d}(\mathbf{k})$, obeys $\mathbf{d}(\mathbf{k}) = -\mathbf{d}(-\mathbf{k})$. For spin-triplet p -wave pairing, the most general form of the order parameter is given by a 3×3 complex matrix, $A_{\mu i} \in \mathbb{C}$, where the components are labelled by $\mu, i \in \{x, y, z\}$.

HQVs with Majorana zero modes in SF^3He

We consider the Anderson-Brinkman-Morel (ABM) state (Anderson and Morel, 1961; Anderson and Brinkman, 1973), as a prototypical example of chiral p -wave states hosting Majorana zero modes. The ABM state is realized in the A-phase of the SF

^3He , which appears in high pressures and high temperatures (Vollhardt and Wölfle, 1990; Volovik, 2003). At temperatures above the SF transition temperature, $T > T_c \approx 1\text{--}2\text{ mK}$, the normal Fermi liquid ^3He maintains a high degree of symmetry

$$G = SO(3)_L \times SO(3)_S \times U(1), \quad (28)$$

where $SO(3)_L$, $SO(3)_S$, and $U(1)$ are the rotation symmetry in space, the rotational symmetry of the nuclear spin degrees of freedom, and the global gauge symmetry, respectively. The tensor $A_{\mu i}$ transforms as a vector with respect to index μ under spin rotations, and, separately, as a vector with respect to index i under orbital rotations. The order parameter of the ABM state is then given by the complex form

$$A_{\mu j} = \Delta e^{i\varphi} \hat{d}_\mu (\hat{m}_j + i\hat{n}_j). \quad (29)$$

The ABM state is the condensation of Cooper pairs with the “ferromagnetic” orbital, and spontaneously breaks the time-reversal symmetry. The orbital part of the order parameter is characterized by a set of three unit vectors forming the triad $(\hat{m}, \hat{n}, \hat{l})$, where $\hat{l} = \hat{m} \times \hat{n}$ denotes the orientation of the orbital angular momentum of Cooper pairs. The remaining symmetry in the ABM state is $H_A = SO(2)_{S_z} \times SO(2)_{L_z-\varphi} \times \mathbb{Z}_2$, where $SO(2)_{S_z}$ is the two-dimensional rotation symmetry in the spin space. The ABM state is also invariant under $SO(2)_{L_z-\varphi}$ which is the combined gauge-orbital symmetry, where the $U(1)$ phase rotation, $\varphi \rightarrow \varphi + \delta\varphi$, is compensated by the continuous rotation of the orbital part about $\hat{l}$, $\hat{m}_j + i\hat{n}_j \rightarrow e^{-i\delta\varphi}(\hat{m}'_j + i\hat{n}'_j)$. In addition, $\mathbb{Z}_2$ is the mod-2 discrete symmetry $(\hat{d}, \hat{m}, \hat{n}) \rightarrow (-\hat{d}, -\hat{m}, -\hat{n})$. The manifold of the order parameter degeneracy is then given by

$$R_A \simeq G/H_A \simeq S^2_S \times SO(3)_{L_z, \varphi} / \mathbb{Z}_2. \quad (30)$$

The two-sphere, S^2_S , is associated with the variation of $\hat{d}$. The degeneracy space has an extra $\mathbb{Z}_2$ symmetry that the change from $\hat{d}$ to $-\hat{d}$ can be compensated by the phase rotation $\varphi \rightarrow \varphi + \pi$.

The topologically stable linear defects in the ABM state are characterized by the group of the integers modulo 4 (Vollhardt and Wölfle, 1990; Volovik, 1992; Salomaa and Volovik, 1987; Volovik, 2003),

$$\pi_1(R_A) \simeq \pi_1(SO(3)/\mathbb{Z}_2) \simeq \mathbb{Z}_4. \quad (31)$$

There exist four different classes of topologically protected linear defects in the dipole-free case. The four linear defects can be categorized by the fractional topological charge,

$$N_A = 0, \frac{1}{2}, 1, \frac{3}{2}, \quad (32)$$

where $N_A = 3/2$ is topologically identical to $N_A = -1/2$. The representatives of $N_A = 0$ and $N_A = 1/2$ classes include continuous vortex such as the Anderson-Toulouse vortex and half quantum vortex (HQV), respectively. Owing to $N_A = 2 = 0$, a pure phase vortex with winding number 2 is continuously deformed into a nonsingular vortex without a core, that is, the Anderson-Toulouse vortex (Anderson and Toulouse, 1977). The $N_A = 1/2$ vortex is a combination of the half-wound $\hat{d}$ -disgyration with a half-integer value of the $U(1)$ phase winding (Fig. 4). The extra $\mathbb{Z}_2$ symmetry allows us to take the half-integer value of the topological charge, because the π -phase jump arising from the half-winding of the $U(1)$ phase ($\varphi = \theta/2$) can be canceled out by the change in the orientation of $\hat{d}$ ($\hat{d} \rightarrow -\hat{d}$). The $N_A = 1$ class includes a pure phase vortex with odd winding number and the radial/tangential disgyrations without phase winding. The latter was originally introduced by de Gennes as l -textures with a singularity line (De Gennes, 1973; Ambegaokar et al., 1974).

The vortex with the fractional charge $N_A = 1/2$ is a harbor for spinless Majorana zero modes. We introduce the center-of-mass coordinate of Cooper pairs, $\mathbf{R} = (\rho, \theta, z)$, as $\hat{\Delta}(\mathbf{k}) \rightarrow \hat{\Delta}(\mathbf{k}, \mathbf{R})$, where $\rho = \sqrt{x^2 + y^2}$. The vortex core is located at $\rho = 0$. The vortex state is subject to the boundary condition at $\rho \rightarrow \infty$ where the orbital angular momentum of the Cooper pair is aligned to the z -axis ($\hat{l} \parallel \hat{z}$) and the $U(1)$ phase φ continuously changes from 0 to $2\pi\kappa$ along the azimuthal (θ) direction,

$$A_{\mu i}(\rho = \infty, \theta) = \Delta e^{i\kappa\theta} \hat{d}_\mu(\theta) (\hat{x}_i + i\hat{y}_i). \quad (33)$$

Owing to the spontaneous breaking of the gauge-orbital symmetry, there are two classes for the vorticity κ : Integer quantum vortices with $\kappa \in \mathbb{Z}$ and HQVs with $\kappa \in \mathbb{Z}/2$. In the HQVs, both the $U(1)$ phase and $\hat{d}$ rotate by π about the vortex center (see Fig. 4). In general, the $\hat{d}$ -texture for HQVs is obtained as

$$\hat{d}(\theta) = \cos(\kappa^{\text{sp}}\theta)\hat{x} + \sin(\kappa^{\text{sp}}\theta)\hat{y}, \quad (34)$$

where κ^{sp} denotes the winding of $\hat{d}$. The HQV is characterized by $(\kappa, \kappa^{\text{sp}}) = (1/2, \pm 1/2)$ while the integer quantum vortex has $(\kappa, \kappa^{\text{sp}}) = (1, 0)$. It is remarkable to notice that since the ABM state is the equal spin pairing state, the order parameter for the HQV is recast into the representation in the spin basis as

$$\hat{\Delta} = \Delta \left[e^{i(\kappa - \kappa^{\text{sp}})\theta} |\uparrow\uparrow\rangle + e^{i(\kappa + \kappa^{\text{sp}})\theta} |\downarrow\downarrow\rangle \right]. \quad (35)$$

Fig. 4 Schematic of the HQV realized in the ABM state. The color map shows the U(1) phase winding from $\varphi = 0$ (red) at $\theta = \pi$ (blue) at $\theta = 2\pi$, and the arrows represent the texture of the $\hat{d}$ -vectors shown in Eq. (34) with $\kappa^{\text{sp}} = 1/2$.

For the HQV with $(\kappa, \kappa^{\text{sp}}) = (1/2, 1/2)$ the $|\uparrow\uparrow\rangle$ Cooper pair possesses the spatially uniform phase while the $|\downarrow\downarrow\rangle$ pair has the phase winding of 2π around the vortex as in a conventional singly quantized vortex. Thus, the vortex-free state in the $\uparrow$ spin sector exhibits fully gapped quasiparticle excitations, while the low-lying structures in HQV are effectively describable with a singly quantized vortex in the $\downarrow$ spin sector, that is, the spin-polarized chiral p -wave SC. An odd-vorticity vortex in the spin-polarized chiral system hosts a single *spinless* Majorana zero mode that obeys non-Abelian statistics. The existence of non-Abelian anyonic zero modes in half quantum vortices was first revealed by Ivanov, who developed the non-Abelian braiding statistics of vortices with spinless Majorana zero modes (Ivanov, 2001).

In the bulk A-phase of the SF ^3He , an obstacle to realizing the HQVs is the formation of continuous vortices with the $\hat{l}$ -texture, which are characterized by the topological charge $N = 0$. As the orientation of the $\hat{l}$ -vector is associated with the orbital motion of the Cooper pair, the $\hat{l}$ -texture can be uniformly aligned in a parallel plate geometry with thickness D . The motion of Cooper pairs is confined in the two-dimensional plane and $\hat{l}$ is locked perpendicular to the plates. Applying a magnetic field further restricts the orientation of $\hat{d}$ to the two-dimensional plane perpendicular to the applied field, which is a favorable situation to stabilize the HQVs. In the parallel plate geometry with $D = 12.5\mu\text{m}$, the measurements of NMR frequency shift observed that the $\hat{d}$ -vectors are confined to the two-dimensional plane perpendicular to $\hat{l}$ (Yamashita et al., 2008). The experiment was performed in a rotating cryostat at ISSP, University of Tokyo. The parallel plates are rotated at the angular velocity $\lesssim 12$ rad/s but no conclusive evidence of HQVs was observed (Yamashita et al., 2008). Although the SF ^3He -A thin film provides an ideal platform for HQVs with Majorana zero modes, the realization of HQVs remains as a challenging task. We also note that point-like solitons in a superfluid ^3He film, such as spin disclinations, were shown to behave as anyons with fractional charges (Volovik and Yakovenko, 1989).

Another promising route to realize HQVs with Majorana zero modes is to artificially introduce well-controlled disorders with high-porosity aerogel. In particular, the polar phase was observed in anisotropic aerogels consisting of uniaxially ordered alumina strands, called the nematic aerogels (Dmitriev et al., 2015; Halperin, 2019) (see Fig. 5A). The order parameter of the polar phase is given by $A_{\mu i} = \Delta e^{i\varphi} \hat{d}_{\mu} \hat{z}_i$, where the orbital state of the Cooper pair ($\hat{z}_i$) is confined by the uniaxially anisotropic disorders. As in the ABM state in the bulk ^3He , the texture of the $\hat{d}$ -vector concomitant with the half-integer vorticity can realize HQVs in the polar phase. In the polar phase, HQVs are energetically preferable to integer quantum vortices at zero magnetic fields and magnetic fields applied along the uniaxial anisotropy (Nagamura and Ikeda, 2018; Mineev, 2014; Regan et al., 2021). Indeed, the HQVs were experimentally observed in nematic aerogels under rotation (Autti et al., 2016). The HQVs were also created by temperature quench via the Kibble-Zurek mechanism (Rysti et al., 2021). As shown in Fig. 5A, the superfluid phase diagram in nematic aerogels is drastically changed from that of the bulk ^3He without disorders, where the polar-distorted A and B (PdA and PdB) phases are stabilized in addition to the polar phase. The NMR measurements performed in Mäkinen et al. (2019) observed that the HQVs survive across the phase transition to the PdA phase. As shown in Fig. 4, the HQV is accompanied by the $\hat{d}$ -soliton in which the $\hat{d}$ orientation rotates. Fig. 5B shows the observed NMR spectra which have satellite peaks in addition to the main peak around the Larmor frequency. The main peak is a signal of the bulk PdA phase. The satellite peak originates from the spin excitation localized at the $\hat{d}$ -solitons connecting pairs of HQVs. The order parameter of the PdA phase is given by $A_{\mu i} = \Delta e^{i\varphi} \hat{d}_{\mu} (\hat{m} + i\varepsilon \hat{n})_i$, where $\hat{m}$ is aligned along the axis of nematic aerogels and $\varepsilon \in (0, 1)$ is the temperature- and pressure-dependent parameter on the distortion of Eq. (29) by nematic aerogels. Although the HQVs in the polar phase host no Majorana zero modes, the low energy structure of the HQVs in the PdA phase is essentially same as that of HQVs in the ABM state and each core may support the existence of *spinless* Majorana zero modes (Mäkinen et al., 2019; Mäkinen et al., 2022). Hence, the survival of the HQVs in the PdA phase is important as a potential platform for topological quantum computation. The elucidation of the nature of the fermionic excitations bound to the HQVs remains as a future problem.

HQVs in SCs

In contrast to the SF ^3He , it is difficult to stabilize HQVs in SCs. The difficulty is attributed to the fact that the mass (charge) current is screened exponentially in the length scale of the penetration depth λ , while such a screening effect is absent in the spin current

Fig. 5 (A) The experimental setup and the phase diagram in the liquid ^3He with nematic disorders and (B) NMR spectra at pressure $P = 7\text{ bar}$ and $T = 0.60T_c$ in the presence of a magnetic field perpendicular to the anisotropy direction of nematic disorders (Mäkinen et al., 2019), where T_c is the critical temperature of the bulk SF ^3He without disorders. The disorders consist of nearly parallel Al_2O_3 strands, where the diameter and mean distance are $d_2 \approx 8\text{ nm}$ and $d_1 \approx 50\text{ nm}$, respectively. In (B), the main peaks with green and magenta colors correspond to the signal of the bulk PdA phase while the satellite peaks originate from the spin excitation bound to the $\hat{d}$ -solitons connecting pairs of HQVs. The satellite peak remains unchanged after the thermal cycling illustrated by purple arrows in (A). Taken from Mäkinen JT, Dmitriev VV, Nissinen J, Rysti J, Volovik GE, Yudin AN, Zhang K, and Eltsov VB (2019) Half-quantum vortices and walls bounded by strings in the polar-distorted phases of topological superfluid ^3He . Nature Communications 10 (1): 237. <https://doi.org/10.1038/s41467-018-08204-8>

(Chung et al., 2007). The HQV is accompanied by the spin current in addition to the mass current, while in the integer quantum vortex, the integer vorticity ($\kappa \in \mathbb{Z}$) and uniform $\hat{d}$ -texture in Eq. (33) induce no spin current. Therefore, the absence of the screening effect on the spin current is unfavorable for the stability of the HQVs relative to the integer quantum vortices, where the later may host spin-degenerate Majorana zero modes. It has also been proposed that configurational entropy at finite temperatures drives the fractionalization of the integer quantum vortices into pairwise HQVs (Chung and Kivelson, 2010). However, no firm experimental evidence for HQVs has been reported in SCs.

Superconducting nanowires

Here we briefly mention recent progress on the search of Majorana zero modes bound at the end points of superconducting nanowires, although we mainly focus on non-Abelian anyons emergent in vortices in this article.

The first idea was proposed by Kitaev that a spinless one-dimensional SC is a platform to host a Majorana zero mode (Kitaev, 2001). Although it was initially thought to be a toy model, it was recognized that a system with the same topological properties can be realized by a semiconductor/SC heterostructure (Alicia, 2012; Sato and Ando, 2017). The key ingredients are a semiconductor nanowire and a large Zeeman magnetic field in addition to the proximitized superconducting gap Δ (Sato et al., 2009, 2010). Consider the Hamiltonian of the semiconductor nanowire under a magnetic field B , $h(p) = p^2/2m - \mu + \lambda p\sigma_y - B\sigma_z$, which appears in the diagonal part of Eq. (13), where m is the mass of an electron and λ is the strength of the spin-orbit coupling. The spin-orbit coupling is not only a source of nontrivial topology, but is also necessary to realize spinless electronic systems together with the large Zeeman field ($B > \mu$). In fact, if the proximitized superconducting gap is taken into account, a combination of spin-orbit coupling with the superconducting gap induces topological odd-parity superconductivity. The topological phase with the spinless Majorana zero mode appears in the higher magnetic field satisfying $B > B_c = \sqrt{\Delta^2 + \mu^2}$.

A direct signature of Majorana zero mode is the quantization of a zero-bias peak in differential conductance, where the height of the zero-bias peak stemming from the Majorana zero mode is predicted to be quantized to the universal conductance value of $2e^2/h$ at zero temperature (Akhmerov et al., 2011; Fulga et al., 2011). Consider a charge-transfer process through a normal metal-SC junction. When an electron with the incident energy E enters from the normal metal to the SC, it forms the Cooper pair with an electron in the Fermi sea at the interface and a hole is created in the normal side as a consequence of momentum conservation. Such a process in which electrons are retroreflected as holes is called Andreev reflection. Let $\phi_E^{\text{in,out}} = [u_E, v_E]^T$ be the two-component wavefunctions of the incident and reflected particles, respectively, where u_E (v_E) accounts for the electron (hole) component. We now consider the scattering problem $\phi_E^{\text{out}}(\mathbf{x}) = S(E)\phi_E^{\text{in}}(\mathbf{x})$. The S -matrix is defined in the particle-hole space as

$$S(E) = \begin{pmatrix} r^{ee}(E) & r^{eh}(E) \\ r^{he}(E) & r^{hh}(E) \end{pmatrix}, \quad (36)$$

which is a unitary matrix $S \in U(2)$. The coefficient r^{ee} ($r^{eh}(E)$) is the amplitude of the normal (Andreev) reflection, and the others are the reflection coefficients of incident holes.

The conductance $G(E)$ at the normal/SC interface is obtained with the conductance quantum $G_0 = e^2/h$ per spin as $G(E) = 2G_0|r^{eh}(E)|^2$. The particle-hole symmetry imposes on the S matrix the constraint, $CS(E)C^{-1} = S(-E)$, leading to $\det S(0) = |r^{ee}(0)|^2 - |r^{eh}(0)|^2$ at $E = 0$. Let V be the unitary matrix defined by $V\phi_0 = (\text{Re}u, \text{Im}u)$. In this basis, the scattering matrix $S(0)$ is transformed as $S'(0) = VS(0)V^\dagger$, where $S'(0) \in O(2)$ is an orthogonal matrix satisfying $S'^\dagger = S'^{-1} = S'^T$ and $\det S(0) = \det S'(0) = \pm 1$. Hence, there are two different processes, a perfect normal reflection process ($\det S(0) = +1$) and a perfect Andreev reflection process ($\det S(0) = -1$). This discrete value, $\det S(0) = \pm 1$, is a topological invariant representing the parity of the number of Majorana zero modes residing at the interface. When $\det S(0) = -1$, there exists at least one Majorana zero mode, which involves the perfect Andreev reflection process and the quantized conductance,

$$G(0) = \frac{2e^2}{h}. \quad (37)$$

The analytical expression of the conductance is obtained by solving the BdG equation and quasiclassical Usadel equation at an interface of the normal metal and unconventional SCs (e.g., p - and d -wave SCs) (Tanaka and Kashiwaya, 1995; Kashiwaya and Tanaka, 2000; Tanaka et al., 2004, 2005), where the conductance per spin reaches $2e^2/h$. The quantized conductance is also related to the Atiyah-Singer index when the Hamiltonian holds the chiral symmetry (Ikegaya et al., 2016).

The conductance has recently been measured in a junction system of InSb-Al hybrid semiconductor-SC nanowire devices. The differential conductance yields the plateau behavior where the peak height reaches values $2e^3/h$ (Zhang et al., 2021). In the device used in the experiment, the tunnel barrier is controlled by applying a gate voltage to the narrow region between the electrode and the region where the proximity effect occurs in the semiconductor wire. In the vicinity of the barrier, the unintentionally formed quantum dot or nonuniform potential formed in the vicinity of the interface gives rise to the formation of nearly zero-energy Andreev bound states. Such Andreev bound states mimic the plateau of $G(0) = 2e^2/h$ even in the topologically trivial region of the magnetic field ($B < B_c$) (Liu et al., 2017; Prada et al., 2020; Cayao and Burset, 2021; Yu et al., 2021; Valentini et al., 2021). From the plateau of $G(0)$, it is not possible to identify whether the observed $G(0) \sim 2e^2/h$ is due to Majorana zero mode or the effect of accidentally formed s bound states. Alternative experimental schemes to distinguish the trivial and topological bound states have been proposed (Liu et al., 2018; Ricco et al., 2019; Yavilberg et al., 2019; Awoga et al., 2019; Zhang and Spänsätt, 2020; Schulenburg and Flensberg, 2020; Pan et al., 2021; Liu et al., 2021; Ricco et al., 2021; Thamm and Rosenow, 2021; Chen et al., 2022; Sugeta et al., 2022).

Vortices in Fe(Se,Te)

The iron-based SC Fe(Se,Te) is a candidate of topologically nontrivial superconducting state supporting Majorana zero modes. In the parent material FeSe, the $3d$ electrons of Fe near the Fermi level mainly contribute to superconductivity, and the p_z orbitals of Se appear on the higher energy. Substitution of Se with Te causes a band inversion between the p_z and $3d$ orbitals. As a result of the band inversion, the normal state of $\text{FeTe}_{1-x}\text{Se}_x$ is topologically nontrivial, and accompanied by the surface Dirac fermions (Zhang et al., 2018). Below the superconducting critical temperature, the superconducting gap is proximitized to the surface Dirac states. It was theoretically pointed out that the topological phase with a spinless Majorana zero mode can be realized when the superconducting proximity effect occurs in the Dirac fermion system (Sato, 2003; Fu and Kane, 2008). Therefore, the surface state of Fe(Se,Te) is a topological superconducting state. When a magnetic field is applied to Fe(Se,Te), the vortex lines penetrate to the surface state and the zero energy state appears. The wave function of the zero mode is tightly bound at the intersection of the vortex line and the surface (Hosur et al., 2011; Kawakami and Hu, 2015).

When a magnetic field is applied to an SC, a quantized vortex penetrates. The magnetic flux is accompanied by the $2\pi m$ winding of the $U(1)$ phase and the superconducting gap vanishes. In other words, a quantized vortex can be regarded as a quantum well with a radius of ξ and a height of Δ . Hence, the Andreev bound states are formed and the level spacing between them is on the order of Δ^2/ϵ_F , where the level spacing is about $100\text{--}200\text{ }\mu\text{eV}$ in Fe(Se,Te). In the topological phase, the lowest level has the exact zero energy, and the quasiparticle behaves as Majorana fermion. Ultra-low temperature STM/STS with high energy resolution observed a pronounced zero-bias conductance peak (Machida et al., 2019). If a Majorana zero mode is bound to the vortex, the conductance should be quantized to the universal value $2e^2/h$ independent of tunnel barriers. In the tunneling spectroscopy performed while changing the distance between the sample surface and the STM tip, the height of the zero-bias conductance peak is approximately 0.6 times as large as the universal value stemming from the Majorana zero mode (Zhu et al., 2020). Although $2e^2/h$ has not been reached, this plateau structure strongly suggests the existence of Majorana zero modes because it cannot be explained by non-Majorana vortex bound states.

Topological quantum computation

Quantum computation based on the braiding of Majorana zero modes is basically along the two directions: implementation of quantum gates and measurement based quantum computation. The unitary evolution of the qubits is controlled by a set of discrete unitary operations, that is, quantum gates. The simple example of the quantum gates acting on a single qubit is the set of the Pauli gates, which are given by the three Pauli matrices $X \equiv \sigma_x$, $Y \equiv \sigma_y$, and $Z \equiv \sigma_z$. The multiqubit gate operation can be implemented by a combination of a set of single-qubit gates and the controlled-NOT (CNOT) gate. According to the Solovay-Kitaev theorem (Nielsen and Chuang, 2010), an arbitrary single-qubit gate can be approximated by a sequence of the discrete gate operations (H , S , T), where $H = (X + Z)/\sqrt{2}$, $S = \sqrt{Z}$, and $T = \sqrt{S}$ are the Hadamard gate, the single-qubit 4π rotation, and the T -gate ($\pi/8$ -gate), respectively. Universal quantum computation can be implemented by a sequence of the single-qubit gates (H , S , T) and the CNOT gate.

In Majorana qubits, the Pauli gates are expressed in terms of the braiding operations as $X = iU_{23}^2$, $Y = iU_{31}^2$, and $Z = iU_{12}^2$, and the Hadamard and S gates are implemented by a combination of such operations as $H = iU_{12}U_{23}U_{12}$ and $S = e^{i\pi/4}U_{12}$. In addition, the CNOT gate can be implemented by a combination of the measurement and braiding operations in two Majorana qubits (i.e., 8 Majorana zero modes) with a single ancilla Majorana qubit (Bravyi, 2006). All the Clifford gates (H , S , CNOT) are realized as a composition of braiding operators in a topologically protected way. According to the Gottesman-Knill theorem, however, quantum circuits only using the elements of Clifford group can be efficiently simulated in polynomial time on a classical computer (Nielsen and Chuang, 2010). Indeed, degenerate quantum states composed of multiple Ising anyons offer tolerant storage of quantum information, and their braiding operations provide all necessary quantum gates in a topologically protected way, except for the non-Clifford T -gate. The T -gate can be implemented only in a topologically unprotected way. For instance, Karzig et al. proposed a scheme to implement the T -gate in a Y-shaped junction accompanied by 4 Majorana zero modes (Karzig et al., 2016).

As mentioned in Section “Non-Abelian anyons,” Fibonacci anyon systems can offer a platform for universal topological quantum computation, where all the single-qubit gates (H , S , T) and the CNOT gate are implemented by the braiding manipulations of the anyons in a topologically protected way (Preskill, 2004; Bonesteel et al., 2005; Hormozi et al., 2007).

Another way to realize universal quantum computation in Majorana qubits is measurement-based quantum computation. It was realized that all braiding manipulations can be implemented in a topologically protected manner by the measurements of topological charges of pairwise anyons (Bonderson et al., 2008, 2009). The process of the quantum information encoded to Majorana qubits can take place by a series of simple projective measurements without braiding Majorana modes. The building block is a Coulomb-blockaded Majorana box which is made from even numbers of Majorana modes in a floating topological SC (Plugge et al., 2017; Karzig et al., 2017; Oreg and von Oppen, 2020).

Symmetry-protected non-Abelian anyons

Symmetry-protected non-Abelian anyons in spinful SCs and SFs were discussed for class D (Ueno et al., 2013; Sato et al., 2014; Fang et al., 2014) and for class DIII (Liu et al., 2014; Gao et al., 2016). In the former (latter) case, mirror reflection symmetry (time reversal symmetry) plays an essential role in the topological protection of non-Abelian nature. In addition, unitary symmetry

protected non-Abelian statistics has been theoretically proposed (Hong et al., 2022). The non-Abelian statistics of vortices supporting multiple Majorana zero modes has also been discussed in Yasui et al. (2011) and Hirono et al. (2012) in the context of high-energy physics.

Mirror and unitary symmetries

As the simple example of symmetry protected non-Abelian anyons, we consider integer quantum vortices in chiral p -wave SCs and $^3\text{He-A}$ (Sato et al., 2014), where each vortex core supports spinful Majorana zero modes. Contrary to the standard wisdom, a pair of Majorana zero modes in integer quantum vortices can be protected by the mirror symmetry and obey the non-Abelian statistics (Ueno et al., 2013; Sato et al., 2014).

Let us consider two-dimensional superconducting film and assume that the normal state holds the mirror symmetry with respect to the xy -plane, $M_{xy}h(\mathbf{k})M_{xy}^\dagger = h(\mathbf{k})$, where $\mathbf{k} = (k_x, k_y)$ is the two-dimensional momentum and the mirror operator is defined as $M_{xy} = i\sigma_z$. The nontrivial topological properties are characterized by the first Chern number in each mirror subsector. When $\Delta(\mathbf{k})$ obeys $M_{xy}\Delta(\mathbf{k})M_{xy}^\dagger = \eta\Delta(\mathbf{k})$ ($\eta = \pm$), the BdG Hamiltonian is commutable with the mirror reflection operator in the particle-hole space, $\mathcal{M}^\eta$, as

$$[\mathcal{M}^\eta, \mathcal{H}(\mathbf{k})] = 0, \quad \mathcal{M}^\eta = \begin{pmatrix} M_{xy} & 0 \\ 0 & \eta M_{xy}^* \end{pmatrix}. \quad (38)$$

Thus, the eigenstates of $\mathcal{H}(\mathbf{k})$ are the simultaneous eigenstates of $\mathcal{M}^\eta$. Let $|u_n^{(\lambda)}(\mathbf{k})\rangle$ and $E_n^{(\lambda)}$ be the wavefunction and eigenenergy of the Bogoliubov quasiparticles in each mirror subsector, where the $\lambda = \pm i$ are the eigenvalues of $\mathcal{M}^\eta$. Then, the first Chern number is defined in each mirror subsector,

$$\text{Ch}_1^{(\lambda)} = \frac{i}{2\pi} \int \mathcal{F}^{(\lambda)} \in \mathbb{Z}, \quad (39)$$

where $\mathcal{F}^{(\lambda)} = d\mathcal{A}^{(\lambda)}$ is the Berry curvature in each mirror subsector and $\mathcal{A}_\mu^{(\lambda)}(\mathbf{k}) = \sum_{E_n^{(\lambda)} < 0} \langle u_n^{(\lambda)}(\mathbf{k}) | \partial_{\mathbf{k}_\mu} u_n^{(\lambda)}(\mathbf{k}) \rangle$. The nonzero value ensures the existence of the zero energy state in the λ subsector. For the $^3\text{He-A}$ thin film and chiral p -wave SCs, $|\text{Ch}_1^{(\lambda)}| = 1$ in each mirror subsector, implying that integer quantum vortices support two Majorana zero modes per each core.

Multiple Majorana zero modes behave as non-Abelian anyons only when the mirror subsector holds the particle-hole symmetry, which are referred to as mirror Majorana zero modes. The condition for each mirror subsector to maintain the particle-hole symmetry is given by (Ueno et al., 2013; Sato et al., 2014)

$$\{\mathcal{C}, \mathcal{M}^\eta\} = 0. \quad (40)$$

For integer quantum vortices, the condition depends on the orientation of the $\mathbf{d}$ -vector. For $\hat{\mathbf{d}} \parallel \hat{\mathbf{z}}$, the mirror subsector supports its own particle-hole symmetry, but otherwise the subsector does not maintain the particle-hole symmetry and belongs to class A.

Now let us clarify the non-Abelian statistics of spin-degenerate Majorana modes. Consider $2N$ integer quantum vortices. Two Majorana zero modes bound at the i th vortex are denoted by γ_λ^i with mirror eigenvalues $\lambda = \pm i$. The Majorana zero modes satisfy the self-conjugate condition $\gamma_\lambda^i = (\gamma_{\lambda'}^i)^\dagger$ and the anticommutation relation, $\{\gamma_\lambda^i, \gamma_{\lambda'}^j\} = 2\delta_{ij}\delta_{\lambda\lambda'}$. In contrast to spinless Majorana zero modes, there are two possibilities to form a complex fermion: (i) intervortex pairs, $c_{ij}^\dagger \equiv (\gamma_\lambda^i + i\gamma_{\lambda'}^j)/2$ and (ii) intravortex pairs, $\psi_i \equiv (\gamma_{\lambda=-i}^i + i\gamma_{\lambda=-i}^i)/2$ (see Fig. 6A and B). In the former case (i), the exchange operators of the i th and j th vortices are defined in a manner similar to that for spinless Majorana zero modes as

$$U_{ij}^{\lambda\dagger} \gamma_\lambda^i U_{ij}^\lambda = \gamma_{\lambda'}^j, \quad U_{ij}^{\lambda\dagger} \gamma_{\lambda'}^j U_{ij}^\lambda = -\gamma_\lambda^i. \quad (41)$$

The above transformation is realized by the unitary operator,

$$U_{ij}^\lambda = \exp\left(\frac{\pi}{4} \gamma_\lambda^j \gamma_\lambda^i\right) = \frac{1}{\sqrt{2}} \left(1 + \gamma_\lambda^j \gamma_\lambda^i\right), \quad (42)$$

Similarly to U_{ij} and U_{jk} in spinless Majorana zero modes, the exchange operators U_{ij}^λ and U_{jk}^λ defined in each mirror subsector do not commute to each other, which implies the non-Abelian anyon statistics of integer quantum vortices hosting mirror Majorana zero modes.

In the case (ii) (Fig. 6B), a complex fermion is formed as a local pair of two mirror Majorana modes, which also obeys the non-Abelian statistics (Yasui et al., 2012; Sato et al., 2014). The expression of the exchange operator is obtained as $U_{ij} = 1 + \psi_j \psi_i^\dagger + \psi_j^\dagger \psi_i - \psi_j^\dagger \psi_i - \psi_j^\dagger \psi_i + 2\psi_j^\dagger \psi_j \psi_i^\dagger \psi_i$. In general, the exchange operators are not commutable with each other, $[U_{ij}, U_{jk}] \neq 0$. As the operator preserves the fermion number $N_f = \sum_i \psi_i^\dagger \psi_i$, the degenerate ground states are expressed in terms of the occupation number of the complex fermion in each vortex. For example, let us consider the four-vortex state $|1100\rangle$ where the first and second vortices are accompanied by the Dirac zero modes, while the third and fourth are not. Up to a phase factor, this state changes under U_{12} and U_{34} as $|1100\rangle \rightarrow |1100\rangle$ and $|1100\rangle \rightarrow |1010\rangle$, respectively. The complete representations of the exchange operators U_{ij} are presented in Yasui et al. (2012). The extension to non-Abelian statistics of multiple complex fermions was discussed in Yasui et al. (2013).

Fig. 6 Complex fermions formed by intervortex pairs (A) and intravortex pairs (B), where γ_a^j denotes a Majorana zero mode with internal degrees of freedom a (e.g., spin) bound at the j th vortex. (C) Schematic of the exchange of two vortices with multiple Majorana zero modes. (D) When the system holds a unitary symmetry such as the mirror symmetry in Eq. (38), the operation (C) is equivalent to the exchange of two Majorana zero modes in each sector.

When the BdG Hamiltonian maintains the mirror symmetry in Eq. (38), as mentioned above, the braiding of vortices supporting spinful Majorana modes is decomposed into two individual exchanges between Majorana zero modes γ_a^i and γ_a^j in each mirror subsector (see also Fig. 6C and D) and the exchange matrices are represented by Eqs. (41) and (42). This argument is applicable for the systems hosting multiple Majorana modes protected by unitary symmetries (Hong et al., 2022), where the couplings between Majorana zero modes in each core are excluded by the unitary symmetries. The braiding of two vortices with n unitary-symmetry-protected multiple Majorana modes generically reduces to the n independent braiding operations in each sector as

$$U_{ij} = \prod_a U_{ij}^a, \quad (43)$$

where a denotes the internal degrees of freedom of Majorana zero modes. The unitary time evolution representing the braiding process does not dynamically break the unitary symmetry, which prohibits the coupling between Majorana modes in different subsectors labeled by a . The mirror reflection symmetry in Eq. (38) is an example of such symmetry-protected non-Abelian anyons. Another example is the non-Abelian vortices in dense QCD matter which trap multiple Majorana zero modes in each core (Yasui et al., 2010; Fujiwara et al., 2011). As discussed below, such vortices with multiple Majorana zero modes obey the non-Abelian statistics and the braiding matrices are identical with the elements in the Coxeter group (Yasui et al., 2011; Hirono et al., 2012).

Contrary to unitary symmetries, the braiding process, characterized as a unitary evolution, may dynamically break antiunitary symmetry such as the time-reversal symmetry. We note that in contrast to time reversal-broken topological SCs such as superconducting nanowires, topological superconductors with time reversal symmetry do not require an external magnetic field for realizing the topological phase and can keep the topological gap close to the proximity-induced superconducting gap (Haim and Oreg, 2019; Wong and Law, 2012; Zhang et al., 2013). Hence, the Majorana-Kramers pairs leads to longer decoherence time of the stored quantum information (Liu et al., 2014). As mentioned above, however, the braiding process of the Majorana-Kramers pairs may dynamically break the antiunitary symmetry. Such dynamical symmetry breaking gives rise to the local mixing of the Majorana-Kramers pairs (Wölms et al., 2014, 2016; Knapp et al., 2020). Gao et al. proposed the conditions to protect the non-Abelian statistics of the Majorana-Kramers pairs (Gao et al., 2016). In addition, Tanaka et al. examined by numerical simulations the tolerance of non-Abelian braidings of Majorana-Kramers pairs against two types of perturbations which may cause decoherence of Majorana-Kramers pairs (Tanaka et al., 2022): (i) Applied magnetic fields and (ii) the effect of a gate-induced inhomogeneous potential at junctions of superconducting nanowires. The former break time reversal symmetry and generate the energy gap of Majorana states while the latter gives rise to non-Majorana low-energy Andreev bound states (Kells et al., 2012; Liu et al., 2017; Moore et al., 2018b, a; Pan et al., 2020; Pan and Das Sarma, 2020). The numerical simulation revealed that the non-Abelian braiding is successful when the direction of the applied magnetic field preserves the chiral symmetry in the initial and final states of a braiding process, where the chiral symmetry is a combination of time reversal symmetry and mirror symmetry (Tanaka et al., 2022). Remarkably, this tolerance is preserved even when the intermediate states of the braiding process breaks this symmetry. As for (ii), non-Majorana-bound states emergent in gate-induced inhomogeneous potentials make Majorana-Kramers qubits vulnerable to quasiparticle poisoning and disturb the braiding protocol. However, the influence can be ignored when the width of the gate-induced potential is sufficiently smaller than the superconducting coherence length.

Multiple Majorana zero modes and Coxeter group

It has been demonstrated that the non-Abelian statistics of vortices hosting three Majorana zero modes has a novel structure, when the Majorana modes have additional $SO(3)$ symmetry (Yasui et al., 2011; Hirono et al., 2012). The representation of braiding operations in four vortices is given by a tensor product of two matrices, where one is identical to the matrix for the braiding of spinless Majorana zero modes, and the other is a generator of the Coxeter group.

Let γ_a^i ($a = 1, 2, 3$) be the operators of three Majorana zero modes in the i th vortex, belonging to the triplet of $SO(3)$. Consider four vortices hosting three Majorana zero modes in each core. The braiding of these vortices is decomposed into the three individual exchanges between Majorana zero modes γ_a^i and γ_a^j (see Fig. 6C and D). For each component a , Majorana zero modes γ_a^i and γ_a^j under braiding manipulations transform in the same way as Eq. (41) and the exchange matrices, U_{ij}^a , are obtained by $U_{ij}^a \rightarrow U_{ij}^a$ in Eqs. (41) and (42). Then, the representations of U_{ij} for vortices with triplet Majorana zero modes are obtained by the 64×64 matrix, $U_{ij} = \prod_{a=1,2,3} U_{ij}^a$, as in Eq. (43).

We now introduce the complex fermion operators as the nonlocal pairs of Majorana zero modes, $c_{ij}^a = (\gamma_a^i + i\gamma_a^j)/2$. For two vortices (i.e., six Majorana modes), this leads to the 2^3 -fold degenerate ground states and the Hilbert space is spanned by the four basis sets: singlet-even $|1_0\rangle \equiv |0\rangle$ (vacuum) and triplet-even $|3_2\rangle \equiv \frac{1}{2!} \epsilon^{abc} c_{ij}^{b\dagger} c_{ij}^{c\dagger} |0\rangle$ (occupied by two fermions) for even fermion parity and singlet-odd $|1_3\rangle \equiv \frac{1}{3!} \epsilon^{abc} c_{ij}^{a\dagger} c_{ij}^{b\dagger} c_{ij}^{c\dagger} |0\rangle$ (occupied by three fermions) and triplet-odd $|3_1\rangle \equiv c_{ij}^{a\dagger} |0\rangle$ (occupied by single fermion). In the case of four vortices, the ground-state degeneracy is $2^6 = 64$ and the bases of the Hilbert space are singlet (1), triplet (3), and quintet (5) states, which are further divided in terms of the fermion parity. The exchange operator is expressed as a product of two $SO(3)$ invariant unitary operators,

$$U_{ij} = \prod_{a=1,2,3} U_{ij}^a = \sigma_{ij} h_{ij} \quad (44)$$

where both matrices are given in terms of γ_i^a as

$$\sigma_{ij} = \frac{1}{2} \left(1 - \gamma_j^1 \gamma_j^2 \gamma_i^1 \gamma_i^2 - \gamma_j^2 \gamma_j^3 \gamma_i^2 \gamma_i^3 - \gamma_j^3 \gamma_j^1 \gamma_i^3 \gamma_i^1 \right), \quad (45)$$

and

$$h_{ij} = \frac{1}{\sqrt{2}} \left(1 - \gamma_j^1 \gamma_j^2 \gamma_j^3 \gamma_i^1 \gamma_i^2 \gamma_i^3 \right). \quad (46)$$

While the matrices h_{ij} are a natural extension of that originally introduced in Ivanov (2001), the matrices σ_{ij} are proper to vortices with three or more Majorana zero modes. It was demonstrated that the matrices σ_{ij} are identified with the elements in the Coxeter group which satisfies the relations

$$(\sigma_{ij})^2 = 1, \quad (\sigma_{ij} \sigma_{jk})^3 = 1, \quad (\sigma_{ij} \sigma_{kl})^2 = 1. \quad (47)$$

The Coxeter group is a symmetry group of polytopes in high dimensions such as a triangle and a tetrahedron. The exchange operators acting on the singlet (1) and triplet (3) are identified with the elements in the Coxeter group, such as a 2-simplex (triangle) under the reflections for the singlet and a 3-simplex (tetrahedron) under the reflections for the triplet (Yasui et al., 2011). The decomposition of the braiding operators U_{ij} in the $SO(3)$ triplet was generalized to the Majorana zero modes of arbitrary odd $n_M \geq 3$ with $SO(n_M)$ symmetry (Hirono et al., 2012).

Such multiple Majorana zero modes were first found in Yasui et al. (2010) and Fujiwara et al. (2011) inside the cores of color flux tubes (“non-Abelian” vortices) (Balachandran et al., 2006; Nakano et al., 2008; Eto and Nitta, 2009; Eto et al., 2014) in QCD matter (Alford et al., 2008). They were also discussed in edges of a topological superconducting wire coupled to a normal lead (Kashuba and Timm, 2015).

Non-Abelian vortex anyons

Here we introduce non-Abelian anyons made of bosonic excitations, which are non-Abelian vortices obeying a non-Abelian statistics (Bais, 1980; Wilczek and Wu, 1990; Bucher, 1991; Brekke et al., 1993; Lo and Preskill, 1993; Lee, 1994; Brekke et al., 1997; Mawson et al., 2019). These non-Abelian vortices are sometime called fluxons.²

Non-Abelian vortices

When a symmetry G , that is either global or local, is spontaneously broken into its subgroup H , there appears an order parameter space

$$M \simeq G/H \quad (48)$$

²Here, the term “flux” originally comes from the fact that they were proposed in gauge theory where non-Abelian symmetry is gauged in the context of high energy physics (Bais, 1980). In this article, we consider only global non-Abelian symmetry relevant for condensed matter physics and they do not carry non-Abelian fluxes.

Fig. 7 Exchange of two vortices. (A) Two closed paths α and β encircle two vortices. (B) Exchange them counterclockwise.

parameterized by Nambu-Goldstone modes. The first homotopy group of the order parameter space

$$\pi_1(G/H) \simeq \pi_0(H) \quad (49)$$

is responsible for the existence of quantum vortices, where we have assumed that G is semisimple. We further have

$$\pi_0(H) \simeq H/H_0 (\simeq H \text{ for a discrete group } H) \quad (50)$$

with a normal subgroup H_0 of H . When $\pi_1(G/H)$ is Abelian (and thus H/H_0 (for semisimple G) is Abelian), vortices are Abelian, while when it is non-Abelian, vortices are non-Abelian (Balachandran et al., 1984; Alford et al., 1990, 1991, 1992).

One of characteristic features of non-Abelian vortices is that H is not globally defined (or multivalued): the unbroken symmetry H_θ depends on the azimuthal angle θ around a non-Abelian vortex as $H_\theta = g(\theta)H_{\theta=0}g^{-1}(\theta)$ with $g(\theta) \in G$, $g(0) = 1$ and $g(2\pi)$ taking a disconnected component of H/H_0 , see Eq. (50). Then, after an adiabatic transport along a loop encircling the non-Abelian vortex, the unbroken symmetry at $\theta = 2\pi$ does not have to come back: $H_{\theta=2\pi} \neq H_{\theta=0}$. This is called *topological obstruction*, and the symmetry H is topologically broken down to a subgroup $K \equiv \{h | [h, g(2\pi)] = 0, h \in H\}$ which is single-valued and globally defined (Balachandran et al., 1984; Alford et al., 1990). This is also called *topological symmetry breaking*. When G and H are local gauge symmetries, it gives a non-Abelian Aharonov-Bohm effect (Bais, 1980; Wilczek and Wu, 1990; Bucher, 1991; Alford et al., 1990, 1991, 1992). Another related feature is the existence of nonlocal charges, called Cheshire charges, existing among separated vortices (Preskill and Krauss, 1990; Alford et al., 1990; Bucher et al., 1992).

Let $\alpha, \beta \in \pi_1(G/H)$ being closed passes enclosing two vortices. Then, if one adiabatically transports the vortex α around the vortex β counterclockwise, the vortex α transforms as (see Fig. 7B)

$$\alpha \rightarrow \beta\alpha\beta^{-1}. \quad (51)$$

Therefore, when one exchanges a pair (α, β) counterclockwise, they transform as

$$(\alpha, \beta) \rightarrow (\beta, \beta\alpha\beta^{-1}). \quad (52)$$

The first homotopy group π_1 is a based fundamental group for which every loop starts from a fixed point O . Instead of it, the conjugacy classes

$$[\alpha] = \beta\alpha\beta^{-1}, \quad \forall \beta \in \pi_1(G/H) \quad (53)$$

characterize individual vortices as can be seen from Eqs. (51) and (52). Two vortices corresponding to two different elements in the same conjugacy class are *indistinguishable* even though they are not the same.

Non-Abelian first homotopy groups significantly control the dynamics of vortices. In two spatial dimensions, scattering of such non-Abelian vortices was discussed in the case that G and H are local gauge symmetries (Wilczek and Wu, 1990; Bucher, 1991; Lo and Preskill, 1993). In three spatial dimensions, vortices are lines. When two vortex lines collide in three spatial dimensions, the fate is determined by corresponding elements of the first homotopy group. When these elements commute, the two vortices pass through or reconnect each other if these elements are identical. On the other hand, when these elements are noncommutative, the third vortex bridging them must be created (Poenaru and Toulouse, 1977; Mermin, 1979; Kobayashi et al., 2009).

Examples of non-Abelian vortices

Nematic liquid crystals

Let us start from nematic liquid crystals focusing on uniaxial nematics (UNs), and D_2 - and D_4 -biaxial nematics (BNs).

UN liquid crystals

The order parameter of UNs is an unoriented rod. The rotational symmetry $G = SO(3)$ is spontaneously broken down to $H \simeq O(2)$, which implies the order parameter manifold

$$\frac{G}{H} = \frac{SO(3)}{O(2)} \simeq \frac{SU(2)}{Pin(2)} \simeq S^2/\mathbb{Z}_2 \simeq \mathbb{R}P^2, \quad (54)$$

which is a real projective space of two dimensions, where $SU(2)$ and $Pin(2)$ are double covering groups of $SO(3)$ and $O(2)$, respectively. Since the fundamental group $\pi_1(\mathbb{R}P^2) = \mathbb{Z}_2$ is Abelian, this does not admit non-Abelian vortices. These vortices are called Alice strings (when G and H are local gauge symmetries) (Schwarz, 1982). Around the Alice string, $SO(2) \subset H$ is not globally defined and H is topologically broken to $K \simeq \mathbb{Z}_2$.

D_2 -BN liquid crystals (Poenaru and Toulouse, 1977; Volovik and Mineev, 1977; Mermin, 1979; Balachandran et al., 1984)

Cholesteric liquid crystals (chiral nematic liquid crystals) can also have the same order parameter space with D_2 -BN liquid crystals (Lavrentovich and Kleman, 2001) and all the following discussions hold. The order parameter of BNs is a set of two unoriented rods of different lengths orthogonal to each other. The (unbroken) symmetry is the dihedral group D_2 keeping a rectangular invariant. Thus, the rotational symmetry $G = SO(3)$ is spontaneously broken down to

$$H \simeq D_2 = \left\{ \mathbf{1}_3, I_x = \begin{pmatrix} +1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, I_y = \begin{pmatrix} -1 & 0 & 0 \\ 0 & +1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, I_z = \begin{pmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & +1 \end{pmatrix} \right\}. \quad (55)$$

Note that $D_2 \simeq \mathbb{Z}_2 \times \mathbb{Z}_2$ is Abelian. The order parameter manifold is

$$G/H = SO(3)/D_2 \simeq SU(2)/\mathbb{Q}, \quad (56)$$

where the quaternion group $\mathbb{Q}$ are universal (double) covering group of D_2 :

$$\mathbb{Q} = \{\pm \mathbf{1}_2, \pm i\sigma_x, \pm i\sigma_y, \pm i\sigma_z\}. \quad (57)$$

Note that $H^* \simeq \mathbb{Q}$ is a non-Abelian group while $H \simeq D_2$ is an Abelian group. This breaking can occur for instance by five real-scalar order parameters belonging to spin-2 representation of $SO(3)$, which is a traceless symmetric 3×3 tensor A with real components, taking a form of

$$A = \text{diag}(1, r, -1-r). \quad (58)$$

The first homotopy group is isomorphic to the quaternion group $\mathbb{Q}$ in Eq. (57)

$$\pi_1(SU(2)/\mathbb{Q}) \simeq \mathbb{Q}. \quad (59)$$

The elements in Eq. (57) correspond to the ground state ($\mathbf{1}_2$), spin vortices of 2π rotation ($-\mathbf{1}_2$), and spin vortices of $\pm\pi$ rotation about the x, y, z -axes ($\pm i\sigma_x, y, z$). These vortex configurations at the large distance can be asymptotically written as

$$A \sim O(\theta)A_{\theta=0}O^T(\theta), \quad O(\theta) \in SO(3) \quad (60)$$

with the azimuthal angle θ . The concrete forms of $O(\theta)$'s are given in Table 1. Corresponding $SU(2)$ elements $g(\theta)$ can be defined as a double covering of $SO(3)$ with $g(2\pi) \in \pi_1(G/H)$. A spin vortex of 2π rotation ($-\mathbf{1}_2$) and a spin vortex of π rotation ($\pm i\sigma_a$) ($a = x, y, z$) are given by

$$\begin{aligned} g(\theta) &= \exp\left(\pm i \frac{\theta}{2} \sigma \cdot \mathbf{n}\right) = \cos \frac{\theta}{2} \mathbf{1}_2 \pm i \sigma \cdot \mathbf{n} \sin \frac{\theta}{2}, \\ g(\theta) &= \exp\left(\pm i \frac{\theta}{4} \sigma_a\right) = \cos \frac{\theta}{4} \mathbf{1}_2 \pm i \sigma_a \sin \frac{\theta}{4}, \end{aligned} \quad (61)$$

respectively, with a unit three-vector $\mathbf{n}$, giving the elements of $\pi_1(G/H)$ at $\theta = 2\pi$: $g(2\pi) = -\mathbf{1}_2$ and $g(2\pi) = \pm i\sigma_a$, respectively. While the former is Abelian because $[g(2\pi), H^*] = 0$ (even though $g(2\pi) \neq g(0)$), the latter is non-Abelian because $[g(2\pi), H^*] \neq 0$ with the universal covering $H^* \simeq SU(2)$,³ and H^* is topologically broken to $K_a^* = \{\pm \mathbf{1}_2, \pm i\sigma_a\}$.

³Note that $[O(2\pi), H] = 0$, and thus the criterion of non-Abelian property should be considered in the universal covering group H^* but not in H .

Table 1 Asymptotic configurations of spin vortices in D_2 -BNs: the fundamental group elements $g(2\pi) \in \pi_1(G/H)$, the $SU(2)$ elements $g(\theta) \in SU(2)$, $O(2\pi)$, and the $SO(3)$ group elements $O(\theta) \in SO(3)$, acting on the order parameter A as Eq. (60). The group actions $O(\theta)$ and $g(\theta)$ for a spin vortex of 2π rotation ($-\mathbf{1}_2$) can be a rotation around any axis along the unit vector $\mathbf{n}$. L_i are 3×3 spin-1 matrices $[L_i]_{jk} = -i\epsilon_{ijk}$.

$g(2\pi) \in \pi_1(G/H)$	$\mathbf{1}_2$	$-\mathbf{1}_2$	$\pm i\sigma_x$	$\pm i\sigma_y$	$\pm i\sigma_z$
$g(\theta)$	$\mathbf{1}_2$	$\exp(i\frac{\theta}{2}\mathbf{n}\cdot\sigma)$	$\exp(\pm i\frac{\theta}{4}\sigma_x)$	$\exp(\pm i\frac{\theta}{4}\sigma_y)$	$\exp(\pm i\frac{\theta}{4}\sigma_z)$
$O(2\pi)$	$\mathbf{1}_3$	$\mathbf{1}_3$	l_x	l_y	l_z
$O(\theta)$	$\mathbf{1}_3$	$\exp(i\theta\mathbf{n}\cdot\mathbf{L})$	$\exp(\pm i\frac{\theta}{2}L_x)$	$\exp(\pm i\frac{\theta}{2}L_y)$	$\exp(\pm i\frac{\theta}{2}L_z)$

The elements in Eq. (57) are grouped to the conjugacy classes, Eq. (53), consisting of five elements:

$$\{\mathbf{1}_2\}, \{-\mathbf{1}_2\}, \{\pm i\sigma_x\}, \{\pm i\sigma_y\}, \{\pm i\sigma_z\}. \quad (62)$$

This follows for instance from $(i\sigma_y)^{-1}(i\sigma_x)(i\sigma_y) = -i\sigma_x$, implying that a vortex corresponding to $i\sigma_x$ becomes $-i\sigma_x$ when it travels around a vortex corresponding to $i\sigma_y$. Thus, the vortices corresponding to $i\sigma_x$ and $-i\sigma_x$ are *indistinguishable* although they are not the same. From $(i\sigma_a)(-i\sigma_a) = \mathbf{1}_2$ ($a = x, y, z$), vortices belonging to the same conjugacy class are antiparticles of each other, and thus they are similar to Majorana fermions discussed in the last section.

In three spatial dimensions, this phenomenon of noncommutativity appears as follows: when two vortex lines corresponding to $i\sigma_x$ and $i\sigma_y$ collide in three spatial dimensions, the third vortex bridging them is created (Poernaru and Toulouse, 1977; Mermin, 1979).

D_4 -BN liquid crystals

The order parameter of D_4 BNs is a set of two unoriented indistinguishable rods of the *same* lengths orthogonal to each other. In this case, the (unbroken) symmetry is a dihedral group D_4 keeping a square invariant:

$$G/H = SO(3)/D_4 \simeq SU(2)/D_4^*, \quad (63)$$

where M^* denotes a universal covering group of M . The fundamental group is given by

$$\pi_1(SU(2)/D_4^*) \simeq D_4^* \quad (64)$$

with the sixteen elements

$$\{\pm \mathbf{1}_2, \pm i\sigma_x, \pm i\sigma_y, \pm i\sigma_z, \pm C_4, \pm C_4^{-1}, \pm i\sigma_x C_4, \pm i\sigma_x C_4^{-1}\} \quad (65)$$

with $C_4 \equiv e^{i\frac{\pi}{2}\sigma_z} = (1/\sqrt{2})(\mathbf{1}_2 + i\sigma_z)$. Note $(C_4)^2 = i\sigma_z$ and $(C_4)^4 = -\mathbf{1}_2$. The conjugacy classes consist of the following seven elements

$$\{\mathbf{1}_2\}, \{-\mathbf{1}_2\}, \{\pm i\sigma_x, \pm i\sigma_y\}, \{\pm i\sigma_z\}, \{C_4, C_4^{-1}\}, \{-C_4, -C_4^{-1}\}, \{\pm i\sigma_x C_4, \pm i\sigma_x C_4^{-1}\}. \quad (66)$$

Since $-C_4 = C_4^3$ ($-C_4^{-1} = C_4^{-3}$), vortices of these elements have more energy than those of C_4 and C_4^{-1} . This symmetry breaking of D_4 nematics can be realized by a higher rank tensor order parameter (Mietke and Dunkel, 2022), in which more generally D_n nematic liquid crystals were also discussed.

Spinor BECs

Next we provide examples of spinor BECs (Kawaguchi and Ueda, 2012). The order parameter of spin-2 BECs is a traceless symmetric 3×3 tensor A with *complex* components transforming under the symmetry $G = U(1) \times SO(3)$ as

$$A \rightarrow e^{i\theta} g A g^T, \quad e^{i\theta} \in U(1), \quad g \in SO(3). \quad (67)$$

Phases of condensations with total angular momentum two are classified by Mermin (Mermin, 1974). They are nematic, cyclic, and ferromagnetic phases. All phases are theoretically possible in the case of spin-2 BECs. The spin-2 BECs are experimentally realized by ^{87}Rb atoms for which the phase is around the boundary between cyclic phase and ferromagnetic phase, see for example, Tojo et al. (2009). Here, we discuss nematic and cyclic phases which host non-Abelian vortex anyons. In the next section, we discuss 3P_2 SF which is in the nematic phase.

BN phases in spin-2 BEC (Song et al., 2007; Uchino et al., 2010; Kobayashi et al., 2012; Borgh and Ruostekoski, 2016)

The nematic phase consists of three degenerate phases: the UN, D_2 - and D_4 -BN phases. The order parameters of the UN, D_2 - and D_4 -BN phases are given by

$$\begin{aligned}
 \text{UN} : A &\sim \text{diag}(1, -1/2, -1/2), \\
 D_2\text{-BN} : A &\sim \text{diag}(1, r, -1-r), \\
 D_4\text{-BN} : A &\sim \text{diag}(1, -1, 0),
 \end{aligned} \tag{68}$$

respectively, where $r \in \mathbb{R}$ and $-1 < r < -1/2$. In the $D_2\text{-BN}$ phase, the limits $r \rightarrow -1/2, -1$ correspond to UN and $D_4\text{-BN}$ phases, respectively. The symmetry breaking patterns and the order parameter manifolds are

$$\begin{aligned}
 \text{UN} : \frac{G}{H} &= U(1) \times \frac{SO(3)}{O(2)} \simeq U(1) \times \mathbb{R}P^2, \\
 D_2\text{-BN} : \frac{G}{H} &= U(1) \times \frac{SO(3)}{D_2} \simeq U(1) \times \frac{SU(2)}{\mathbb{Q}}, \\
 D_4\text{-BN} : \frac{G}{H} &= \frac{U(1) \times SO(3)}{D_4} \simeq \frac{U(1) \times SU(2)}{D_4^*}.
 \end{aligned} \tag{69}$$

These phases are continuously connected by the parameter r interpreted as a quasi-Nambu-Goldstone mode. The degeneracy is lifted by quantum effects and either of these phases remains as the ground state (Uchino et al., 2010).

The $D_2\text{-BN}$ and $D_4\text{-BN}$ admit non-Abelian vortices. The order parameters of the UN and $D_2\text{-BN}$ phases of spin-2 BECs are merely products of the $U(1)$ phonon and the order parameters of the corresponding nematic liquids. Thus, we concentrate on the $D_4\text{-BN}$ phase hereafter. The fundamental group of the $D_4\text{-BN}$ phase is given by

$$\pi_1 \left(\frac{U(1) \times SU(2)}{D_4^*} \right) \cong \mathbb{Z} \times_h D_4^* \tag{70}$$

where $\times_h$ is defined in Kobayashi et al. (2012). This consists of the following sixteen elements

$$\begin{aligned}
 &\{(N, \pm \mathbf{1}_2), (N, \pm i\sigma_x), (N, \pm i\sigma_y), (N, \pm i\sigma_z), \\
 &\quad \left(N + \frac{1}{2}, \pm C_4\right), \left(N + \frac{1}{2}, \pm i\sigma_x C_4\right), \left(N + \frac{1}{2}, \pm C_4^{-1}\right), \left(N + \frac{1}{2}, \pm i\sigma_x C_4^{-1}\right)\}
 \end{aligned} \tag{71}$$

where the first and second elements of a pair $(\cdot, \cdot)$ denote the circulation κ ($U(1)$ winding number) and an $SU(2)$ element, respectively with $N \in \mathbb{Z}$. Here $C_4 \equiv e^{i\frac{\pi}{2}\sigma_z} = (1/\sqrt{2})(\mathbf{1}_2 + i\sigma_z)$ satisfying $C_4^4 = -\mathbf{1}_2$. The conjugacy classes of Eq. (71) are composed of seven elements for each N :

$$\begin{aligned}
 \text{(I)} & \quad \{(N, \mathbf{1}_2)\}, \\
 \text{(II)} & \quad \{(N, -\mathbf{1}_2)\}, \\
 \text{(III)} & \quad \{(N, \pm i\sigma_x), (N, \pm i\sigma_y)\}, \\
 \text{(IV)} & \quad \{(N, \pm i\sigma_z)\}, \\
 \text{(V)} & \quad \left\{ \left(N + \frac{1}{2}, C_4\right), \left(N + \frac{1}{2}, C_4^{-1}\right) \right\}, \\
 \text{(VI)} & \quad \left\{ \left(N + \frac{1}{2}, -C_4\right), \left(N + \frac{1}{2}, -C_4^{-1}\right) \right\}, \\
 \text{(VII)} & \quad \left\{ \left(N + \frac{1}{2}, \pm i\sigma_x C_4\right), \left(N + \frac{1}{2}, \pm i\sigma_x C_4^{-1}\right) \right\}.
 \end{aligned} \tag{72}$$

They describe (I) integer vortices ($N = 0$ corresponds to the vacuum), (II) spin vortices of 2π rotation, (III),(IV) spin vortices of π rotation around the x , y , and z axes, and (V)–(VII) non-Abelian HQVs.

In Section “ 3P_2 Topological SFs,” we see that 3P_2 SFs are in the $D_4\text{-BN}$ phase in a strong magnetic field. There, a singly quantized vortex $(1, \mathbf{1})$ splits into two HQVs $(1/2, C_4)$ and $(1/2, C_4^{-1})$ both in the conjugacy class (V).⁴ When they fuse, they go back to the singly quantized vortex $(1, \mathbf{1})$. However, one of them, for example, $(1/2, C_4^{-1})$ can transform to the other $(1/2, C_4)$ once some other vortex passes through between them because they belong to the same conjugacy class. If they fuse after that, they become $(1, i\sigma_z)$ because $C_4^2 = i\sigma_z$ which is a composite belonging to (IV), of a singly quantized vortex and a spin vortex of π rotation.

Cyclic phase in spin-2 BEC (Semenoff and Zhou, 2007; Kobayashi et al., 2009, 2012)

The order parameter of the cyclic phase is

$$A \sim \text{diag}(1, e^{2\pi i/3}, e^{4\pi i/3}), \tag{73}$$

⁴Topologically a decay into a pair $(1/2, -C_4)$ and $(1/2, -C_4^{-1})$ in the conjugacy class (VI) is also possible, but energetically disfavored.

yielding the symmetry breaking to the tetrahedral group $H \simeq T$ and the order parameter manifold, given by

$$\frac{G}{H} = \frac{U(1) \times SO(3)}{T} \simeq \frac{U(1) \times SU(2)}{T^*} \quad (74)$$

with the universal covering group T^* of T . The fundamental group in the cyclic phase is given by

$$\pi_1\left(\frac{U(1) \times SU(2)}{T^*}\right) \cong \mathbb{Z} \times_h T^* \quad (75)$$

with the 24 elements

$$\begin{aligned} & \{(N, \pm \mathbf{1}_2), (N, \pm i\sigma_x), (N, \pm i\sigma_y), (N, \pm i\sigma_z), \\ & \left(N + \frac{1}{3}, \pm C_3\right), \left(N + \frac{1}{3}, \pm i\sigma_x C_3\right), \left(N + \frac{1}{3}, \pm i\sigma_y C_3\right), \left(N + \frac{1}{3}, \pm i\sigma_z C_3\right), \\ & \left(N - \frac{1}{3}, \pm C_3^2\right), \left(N - \frac{1}{3}, \pm i\sigma_x C_3^2\right), \left(N - \frac{1}{3}, \pm i\sigma_y C_3^2\right), \left(N - \frac{1}{3}, \pm i\sigma_z C_3^2\right)\}, \end{aligned} \quad (76)$$

with the same notation with Eq. (71). Here $C_3 \equiv (1/2)(\mathbf{1}_2 + i\sigma_x + i\sigma_y + i\sigma_z)$ satisfying $(C_3)^3 = -\mathbf{1}_2$. The conjugacy classes of Eq. (76) are composed of the following seven elements for each N (Semenoff and Zhou, 2007):

$$\begin{aligned} \text{(I)} & \quad \{(N, \mathbf{1}_2)\}, \\ \text{(II)} & \quad \{(N, -\mathbf{1}_2)\}, \\ \text{(III)} & \quad \{(N, \pm i\sigma_x), (N, \pm i\sigma_y), (N, \pm i\sigma_z)\}, \\ \text{(IV)} & \quad \left\{\left(N + \frac{1}{3}, C_3\right), \left(N + \frac{1}{3}, -i\sigma_x C_3\right), \left(N + \frac{1}{3}, -i\sigma_y C_3\right), \left(N + \frac{1}{3}, -i\sigma_z C_3\right)\right\}, \\ \text{(V)} & \quad \left\{\left(N + \frac{1}{3}, -C_3\right), \left(N + \frac{1}{3}, i\sigma_x C_3\right), \left(N + \frac{1}{3}, i\sigma_y C_3\right), \left(N + \frac{1}{3}, i\sigma_z C_3\right)\right\}, \\ \text{(VI)} & \quad \left\{\left(N - \frac{1}{3}, C_3^2\right), \left(N - \frac{1}{3}, i\sigma_x C_3^2\right), \left(N - \frac{1}{3}, i\sigma_y C_3^2\right), \left(N - \frac{1}{3}, i\sigma_z C_3^2\right)\right\}, \\ \text{(VII)} & \quad \left\{\left(N - \frac{1}{3}, -C_3^2\right), \left(N - \frac{1}{3}, -i\sigma_x C_3^2\right), \left(N - \frac{1}{3}, -i\sigma_y C_3^2\right), \left(N - \frac{1}{3}, -i\sigma_z C_3^2\right)\right\}. \end{aligned} \quad (77)$$

They describe (I) integer vortices ($N = 0$ corresponds to the vacuum), (II) spin vortices of 2π rotation, (III) spin vortices of π rotation around the x, y, z axes, and (IV)–(VII) $1/3$ -quantum vortices.

Other examples

Another example in condensed matter physics can be found in vortex lines in the dipole-free A-phase of $\text{SF } ^3\text{He}$ (Balachandran et al., 1984; Salomaa and Volovik, 1987). An example in high energy physics can be found in color flux tubes (“non-Abelian” vortices) in high-density QCD matter (Fujimoto and Nitta, 2021a, b, c; Eto and Nitta, 2021).

Fusion rules for non-Abelian vortex anyons

Two non-Abelian vortices belonging to the same conjugacy class are indistinguishable even if they are not identical. For instance, a vortex $a \in \pi_1(G/H)$ and a vortex $b = cac^{-1}$ with $c \in \pi_1(G/H)$ are not the same and thus a and antivortex of b cannot pair annihilate. Nevertheless they are indistinguishable with a help of c . This leads a class of non-Abelian statistics (Brekke et al., 1993; Lo and Preskill, 1993; Lee, 1994; Brekke et al., 1997). Such non-Abelian anyons are called non-Abelian vortex anyons.

In order to discuss non-Abelian vortex anyons, first we define anyons $\{1, \sigma, \tau\}$ appropriately by conjugacy classes of non-Abelian vortices. Then, the fusion rule (3) for non-Abelian vortex anyons can be written as (Mawson et al., 2019)

$$\begin{aligned} \tau \otimes \tau &= N_{\tau\tau}^1 \mathbf{1} \oplus N_{\tau\tau}^\sigma \sigma \oplus N_{\tau\tau}^\tau \tau, \\ \tau \otimes \sigma &= \tau, \quad \sigma \otimes \sigma = \mathbf{1}, \quad x \otimes \mathbf{1} = x, \end{aligned} \quad (78)$$

with $x \in \{1, \sigma, \tau\}$.

Non-Abelian vortex anyons in D_2 -BN

Let us discuss the simplest case. For D_2 -BN liquid crystals or D_2 -BN phases of spin-2 BECs, the conjugacy class is given in Eq. (62). We then define

$$\mathbf{1} = \{+\mathbf{1}_2\}, \quad \sigma = \{-\mathbf{1}_2\}, \quad \tau = \{\pm i\sigma_a\} \quad (79)$$

with a being either x, y , or z . The coefficient N_{ab}^c counts how many ways anyons a and b fuse to an anyon c . The relations $(-i\sigma_a)(+i\sigma_a) = (+i\sigma_a)(-i\sigma_a) = +\mathbf{1}_2$ and $(-i\sigma_a)(-i\sigma_a) = (+i\sigma_a)(+i\sigma_a) = -\mathbf{1}_2$ lead $N_{\tau\tau}^1 = 2$ and $N_{\tau\tau}^\sigma = 2$, respectively. Furthermore, τ anyons do not fuse to τ in this case and then $N_{\tau\tau}^\tau = 0$. We thus reach

$$\begin{aligned}\tau \otimes \tau &= 2\mathbf{1} \oplus 2\sigma, \\ \tau \otimes \sigma &= \tau, \quad \sigma \otimes \sigma = \mathbf{1}, \quad x \otimes \mathbf{1} = x,\end{aligned}\tag{80}$$

with $x \in \{\mathbf{1}, \sigma, \tau\}$. Since two τ -anyons fuse to two different anyons $\mathbf{1}$ and σ , τ anyons are non-Abelian anyons. Comparing this fusion rule with that of the Ising anyons in Eq. (4), we find that these non-Abelian vortex anyons are similar to the Ising anyons. In fact, a τ anyon coincide with its antiparticle, and so similar to a Majorana fermion.

Gathering all $\tau_a = \{\pm i\sigma_a\}$ ($a = x, y, z$) together, we obtain the following fusion formula from the relation $(i\sigma_a)(i\sigma_b) = -\delta_{ab} + \varepsilon_{abc}(-i\sigma_c)$:

$$\begin{aligned}\tau_a \otimes \tau_b &= 2\delta_{ab}\mathbf{1} \oplus 2\delta_{ab}\sigma \oplus 2\varepsilon_{abc}\tau_c \\ \tau_a \otimes \sigma &= \tau_a, \quad \sigma \otimes \sigma = \mathbf{1}, \quad x \otimes \mathbf{1} = x,\end{aligned}\tag{81}$$

with $x \in \{\mathbf{1}, \sigma, \tau_x, \tau_y, \tau_z\}$. In this case, there are the three non-Abelian anyons τ_a coupled to each other.

Non-Abelian vortex anyons in spin-2 BECs

Non-Abelian vortex anyons in spin-2 BECs were studied in Mawson et al. (2019). For the cyclic phase in a spin-2 BEC, $\{\mathbf{1}, \sigma, \tau\}$ are defined by the conjugacy classes (I), (II) and (III) with $N = 0$ in Eq. (77). Then, we have (see Table 2) $N_{\tau\tau}^{\mathbf{1}} = 6$, $N_{\tau\tau}^{\sigma} = 6$, $N_{\tau\tau}^{\tau} = 4$:

$$\begin{aligned}\tau \otimes \tau &= 6\mathbf{1} \oplus 6\sigma \oplus 4\tau, \\ \tau \otimes \sigma &= \tau, \quad \sigma \otimes \sigma = \mathbf{1}, \quad x \otimes \mathbf{1} = x,\end{aligned}\tag{82}$$

with $x \in \{\mathbf{1}, \sigma, \tau\}$. The non-Abelian 1/3-quantum vortices in (IV)–(VII) are also non-Abelian anyons but one cannot restrict to the $N = 0$ sector, and needs infinite numbers of anyons for a closed algebra.

The fusion rule for vortex anyons in the D_4 -BN phase of a spin-2 BEC was also obtained by the conjugacy classes (I)–(IV) in Eq. (72) (Mawson et al., 2019). In this case, τ in the cyclic phase is split into $\tau_1 = \text{III}_0$ and $\tau_2 = \text{IV}_0$. Then, we have $N_{\tau_1\tau_1}^{\mathbf{1}} = 4$, $N_{\tau_1\tau_1}^{\sigma} = 4$, $N_{\tau_1\tau_1}^{\tau_1} = 4$, $N_{\tau_2\tau_2}^{\mathbf{1}} = 2$, $N_{\tau_2\tau_2}^{\sigma} = 2$ with the other components zero:

$$\begin{aligned}\tau_1 \otimes \tau_1 &= 4\mathbf{1} \oplus 4\sigma \oplus 4\tau_1, \\ \tau_2 \otimes \tau_2 &= 2\mathbf{1} \oplus 2\sigma, \\ \tau_i \otimes \sigma &= \tau_i, \quad \sigma \otimes \sigma = \mathbf{1}, \quad x \otimes \mathbf{1} = x,\end{aligned}\tag{83}$$

with $i = 1, 2$ and $x \in \{\mathbf{1}, \sigma, \tau_i\}$. See Table 3. The non-Abelian HQVs in (V)–(VII) are also non-Abelian anyons, but again infinite numbers of anyons are necessary for a closed algebra. The same fusion rule in Eq. (83) should hold for a D_4 -BN liquid crystal, as seen in Eq. (66).

Including Bogoliubov modes, the algebra of vortex anyons is extended to a quantum double (Koonwinder et al., 1999; Mawson et al., 2019). An application to quantum computation was also proposed in Génétay Johansen and Simula (2022).

3P_2 Topological SFs

Finally we discuss the twofold non-Abelian object in a novel topological SF called a 3P_2 SF: The twofold non-Abelian nature is attributed to the fermionic part (Section “Non-Abelian anyons in topological SCs”) and the vortex part (Section “Non-Abelian vortex anyons”). The 3P_2 SF is a condensate of spin-triplet ($S = 1$) p -wave ($L = 2$) Cooper pairs with total angular momentum $J = 2$. In the following, we briefly review 3P_2 SFs in Section “Overview of 3P_2 topological SFs.” In Section “Half quantum vortex in D_4 -BN state,” the stability of a pair of HQVs compared with a singly quantized vortex is discussed. In Section “Non-Abelian anyon in non-Abelian vortex,” we show that a Majorana fermion, a non-Abelian Ising anyon, exists in the core of each HQV.

Overview of 3P_2 topological SFs

Study of 3P_2 SFs was initiated since 1970s (Hoffberg et al., 1970; Tamagaki, 1970; Takatsuka and Tamagaki, 1971; Takatsuka, 1972; Richardson, 1972; Sedrakian and Clark, 2018). On the basis of the analysis of the phase shifts from nucleon-nucleon scattering in a free space, spin-singlet s -wave 1S_0 symmetry is a dominant attractive channel in the inner crust region ($\rho \lesssim 0.5\rho_0$, where $\rho_0 = 0.17\text{fm}^{-3}$ is called the nuclear density) (Tamagaki, 1970). The critical temperature was estimated as 10^8 – 10^{10} K, which is two orders of magnitude smaller than the Fermi energy. For further increase in density $0.7\rho_0 \lesssim \rho \lesssim 3\rho_0$ in the inner core region, the 1S_0 superfluidity is suppressed, and instead the attractive channel of the 3P_2 grows. Because of the attractively strong spin-orbit force, the 3P_2 Cooper pair channels with high angular momentum become more attractive than other 3P pairing symmetry in contrast to the atomic physics where the lower total angular momentum state is favored as in the SF ${}^3\text{He}$ -B phase. The anisotropic form of the Cooper pair is thought to affect the Cooling rate of neutron stars. Extreme conditions of neutron stars are not only high density but also rapid rotation, and a strong magnetic field. Especially, neutron stars accompanied by magnetic field ranging from 10^{15} to 10^{18} G are called magnetars. Rich structures of exotic condensates and vortices explained below may be the origin of the observed *pulsar glitches*, that is, the sudden increase of the angular momentum of neutron stars. Among them, the existence of non-Abelian HQVs in high magnetic fields is responsible for the scaling law of the glitches without any fitting parameters (Marmorini et al., 2020).

In terms of the symmetry point of view, 3P_2 SFs spontaneously break the global gauge symmetry $U(1)_\varphi$ and the simultaneous rotational symmetry in the spin-momentum space $SO(3)_J$ which originally exist in the normal state inside neutron stars. The order parameter of 3P_2 SFs is spanned by 3 by 3 traceless symmetric tensor $A_{\mu i}$, where the 2 by 2 gap function in momentum space can be given by $\hat{\Delta}(\mathbf{k}) = A_{\mu i} \hat{k}_i \hat{\sigma}_\mu \hat{i} \hat{\sigma}_\gamma$. For later convenience, we introduce a representation based on the total angular momentum along the quantization axis, $M = -2, \dots, 2$:

$$A_{\mu i} = \sum_{M=-2}^2 \gamma_M [\Gamma_M]_{\mu i}, \quad (84)$$

where γ_M is a complex wave function of the Cooper pair in the angular momentum sector M . A basis set Γ_M is given for the quantization axis $\hat{w}$ by

$$[\Gamma_{\pm 2}]_{\mu i} = \frac{(\hat{u} \pm i\hat{v})_\mu (\hat{u} \pm i\hat{v})_i}{2}, \quad (85)$$

$$[\Gamma_{\pm 1}]_{\mu i} = \mp \frac{(\hat{u} \pm i\hat{v})_\mu \hat{w}_i + \hat{w}_\mu (\hat{u} \pm i\hat{v})_i}{2}, \quad (86)$$

$$[\Gamma_0]_{\mu i} = \frac{-\hat{u}_\mu \hat{u}_i - \hat{v}_\mu \hat{v}_i + 2\hat{w}_\mu \hat{w}_i}{\sqrt{6}}, \quad (87)$$

where $\hat{u}$, $\hat{v}$, and $\hat{w}$ constitute the orthonormal triad.

From a phenomenological aspect, the Ginzburg-Landau (GL) energy functional invariant under the $SO(3)_J$ and $U(1)_\varphi$ symmetry was obtained for 3P_2 SFs as (Richardson, 1972; Fujita and Tsuneto, 1972; Sauls and Serene, 1978; Muzikar et al., 1980; Sauls et al., 1982)

$$\mathcal{F} = \alpha \text{tr}[AA^*] + \beta_1 |\text{tr} A|^2 + \beta_2 (\text{tr}[AA^*])^2 + \beta_3 \text{tr}[A^2 A^{*2}]. \quad (88)$$

It should be remarked that spin-2 spinor BECs ($L = 0$, $S = 2$) and d -wave superconductivity ($L = 2$, $S = 0$) have similar order parameter structures. The GL functional for the 3P_2 Cooper pairs was minimized by Sauls and Serene by using the correspondence to the $L = 2$ GL functional which was solved by Mermin (Sauls and Serene, 1978; Mermin, 1974). The ground-state solutions are classified into three types of phases determined by $\beta_{i=1, 2, 3}$, as shown in Fig. 8A: nematic phases with time reversal symmetry and the cyclic and ferromagnetic phases as nonunitary state. The microscopic derivation of the GL parameters clarifies that the ground state is the nematic phases in the weak coupling limit (Sauls and Serene, 1978; Sauls, 1980). The order parameter tensor of a nematic phase is given by $A_{\mu i} = \Delta[\hat{u}_\mu \hat{u}_i + r \hat{v}_\mu \hat{v}_i - (1+r) \hat{w}_\mu \hat{w}_i]$ with a real number $r \in [-1, -1/2]$ (see also Eq. 68). The nematic phase has a continuous degeneracy which is lifted by either a magnetic field or sixth-order terms in the GL free energy. For the GL parameters derived from the microscopic model, the UN phase for $r = -1/2$ is favored at zero magnetic field while D_2 -BN ($-1 < r < -1/2$) and D_4 -BN $r = -1$ phases are favored for moderate and strong magnetic fields, respectively (Masuda and Nitta, 2016),

Fig. 8 (A) Phase diagram without magnetic field based on the GL theory. (B) Gap structure of the nematic state. (C) Phase diagram with magnetic field in the weak coupling limit. (D) The momentum resolved local density state at the surface perpendicular to the $\hat{z}$ -axis. The magnetic field is applied parallel (perpendicular) to the surface [top (bottom) panel]. Adapted from Mizushima T, Masuda K, and Nitta M (2017) 3P_2 Superfluids are topological. *Physical Review B* 95 (14): 140503. <https://doi.org/10.1103/PhysRevB.95.140503>. ©2022 American Physical Society.

relevant for magnetars. The schematic images of the gap structures for the UN and D_4 -BN states are shown in Fig. 8B, where the arrows account for the momentum-dependent direction of the d -vector, defined by $d_\mu(\mathbf{k}) = \sum_i A_{\mu i} k_i$. We will discuss other possible states later in the context of the fermionic topology.

The microscopic model of 3P_2 SFs in terms of the fermion degrees of freedom was constructed by Richardson (1972), Tamagaki (1970), Takatsuka and Tamagaki (1971), and Takatsuka (1972): The starting microscopic Hamiltonian is composed of the one-body term H_1 and the interaction term H_2 given, respectively, in the following forms:

$$H_1 = \int d\mathbf{r} \bar{\psi}(\mathbf{r}) [\hat{h}_N(-i\nabla)] \psi(\mathbf{r}), \quad (89)$$

$$H_2 = - \int d\mathbf{r} \sum_{\alpha\beta=x,y,z} \frac{g}{2} T_{\alpha\beta}^\dagger(\mathbf{r}) T_{\alpha\beta}(\mathbf{r}). \quad (90)$$

In the first line, $[\bar{\psi}(\mathbf{r})]_\sigma = \bar{\psi}_\sigma(\mathbf{r})$ and $[\hat{h}_N(-i\nabla)]_{\sigma\sigma'}$ is the sum of the kinetic energy $h_0(-i\nabla)\delta_{\sigma\sigma'} = (-\nabla^2/2m - \mu)\delta_{\sigma\sigma'}$ measured from the chemical potential μ , and the Zeeman energy $-\mathbf{B} \cdot \hat{\boldsymbol{\sigma}}$ for a magnetic field $\mathbf{B} = B\mathbf{n}$. The 3P_2 force with coupling strength $g > 0$ is represented by H_2 with the pair-annihilation operator T defined by $T_{\alpha\beta}(\mathbf{r}) = \sum_{\sigma\sigma'} [t_{\alpha\beta,\sigma\sigma'}(-i\nabla)] \psi_\sigma(\mathbf{r}) \psi_{\sigma'}(\mathbf{r})$, where $\nabla \equiv k_F^{-1} \nabla$. We have introduced a spin-momentum coupling in the pair force via the 2×2 matrix in spin space $\hat{t}_{\alpha\beta}$ defined by $\hat{t}_{\alpha\beta}(-i\nabla) = i\hat{\sigma}_y \{ [\hat{\sigma}_x(-i\nabla_\beta) + \hat{\sigma}_y(-i\nabla_\alpha)]/2\sqrt{2} - \delta_{\alpha\beta} \hat{\boldsymbol{\sigma}} \cdot (-i\nabla)/3\sqrt{2} \}$. Within the mean field approximation, the BdG equation is derived as

$$\tilde{\mathcal{H}}(-i\nabla, \mathbf{R}) \vec{u}_v(\mathbf{R}) = \varepsilon_v \vec{u}_v(\mathbf{R}), \quad (91)$$

$$\tilde{\mathcal{H}}(-i\nabla, \mathbf{R}) = \begin{pmatrix} \hat{h}_N(-i\nabla) & \hat{\Delta}(-i\nabla, \mathbf{R}) \\ -[\hat{\Delta}(-i\nabla, \mathbf{R})]^* & -[\hat{h}_N(-i\nabla)]^* \end{pmatrix}, \quad (92)$$

where the gap matrix is given by $\hat{\Delta}(-i\nabla, \mathbf{R}) = \sum_{\alpha\beta} \frac{i\hat{\sigma}_x \hat{\sigma}_y}{2k_F} \{ 2A_{\alpha\beta}(\mathbf{R})(-i\nabla_\beta) + [(-i\nabla_\beta)A_{\alpha\beta}(\mathbf{R})] \}$. This model was also used to determine the aforementioned GL parameters in the weak coupling limit and was directly investigated within a quasiclassical approximation recently in Mizushima et al. (2017). Even in the presence of the magnetic field, the quasiclassical approximation, where the size of the Fermi surface is treated as an infinite one, predicts that a nematic state is the most stable with parameter r determined by the strength of the magnetic field as in the GL theory. The T - B phase diagram is shown in Fig. 8C. As explained later, the ferromagnetic state appears near T_c when the finite-size correction of the Fermi surface is taken into account. The microscopic analysis reveals the existence of the tricritical point on the phase boundary between the D_4 -BN and D_2 -BN states in the T - B phase diagram shown in Fig. 8C: at temperatures below the tricritical point, the phase transition becomes discontinuous (Mizushima et al., 2017). The existence of the tricritical point was later confirmed in Mizushima et al. (2020) also in the GL theory with higher order terms (up to the eighth order (Yasui et al., 2019a)). In addition to such drastic change in critical phenomena, the advantage of the microscopic model lies in studies of the fermionic topology of the superfluidity. In the following, we explain the fermionic topology of the possible phases of the 3P_2 SFs.

Nematic state

In the weak coupling limit without a magnetic field, the UN state is the ground state. The order parameter tensors of the UN state and the BN state under a magnetic field are already explained above. On the basis of the symmetry of the BdG Hamiltonian, the nematic state is revealed as a topological SF with time reversal symmetry (a class DIII in the classification of topological insulators and SCs). The analysis of the BdG equation in the presence of the boundary clarifies the existence of the gapless surface bound Majorana fermion, the hallmark character of the topological states. The surface Majorana fermion has an Ising spin character

(Chung and Zhang, 2009; Nagato et al., 2009; Volovik, 2010; Mizushima and Machida, 2011), that is, the only external field coupled to the Ising spin gives a mass gap to the Majorana fermion as shown in Fig. 8D. The magnetic field direction giving the gap to the Majorana fermion is the direction perpendicular to the surface, denoted by $\mathbf{n}_\perp$. This is because the surface Majorana fermion is protected not only by the time reversal symmetry but also another key symmetry, which is the magnetic π -rotation symmetry about $\mathbf{n}_\perp$. The magnetic π -rotation symmetry is also called the $\bar{P}_3$ symmetry.⁵ The magnetic π -rotation is the combined operation of the time-reversal and the π rotation. The chiral operator, defined by the combination of particle-hole operation $\mathcal{C}$ and the magnetic π -rotation $\bar{P}_3$ as $\Gamma = \mathcal{C}\bar{P}_3$, commutes with the Hamiltonian $\mathcal{H}(\mathbf{k}_\perp)$ with magnetic field $\mathbf{B} \cdot \mathbf{n}_\perp = 0$ and the chiral symmetric momentum $\mathbf{k}_\perp = k_\perp \mathbf{n}_\perp$ such that $\Gamma : \mathbf{k}_\perp \rightarrow \mathbf{k}_\perp$. Using this commutation relation, a one-dimensional winding number can be introduced as $w_{1d} = -\frac{1}{4\pi i} \int d\mathbf{k}_\perp \text{Tr}[\Gamma \mathcal{H}(\mathbf{k}_\perp) \partial_{k_\perp} \mathcal{H}(\mathbf{k}_\perp)] = 2$, which is unchanged unless the symmetry is broken or the bulk gap is closed. The P_3 symmetry and thus the chiral symmetry is broken by the magnetic field $\mathbf{B} \cdot \mathbf{n}_\perp \neq 0$ which gives a mass gap to the Majorana fermion (the bottom panel of Fig. 8D, where $\mathbf{n}_\perp \parallel \hat{z}$).

Cyclic state

For $-6\beta_1 < \beta_3 < 0$ based on the basis of $SO(3)_I$ invariant GL functional, the cyclic state is the ground state. The order parameter tensor has a form of $A_{\mu i} = \Delta[\hat{u}_\mu \hat{u}_i + \omega \hat{v}_\mu \hat{v}_i + \omega^2 \hat{w}_\mu \hat{w}_i]$ with $\omega = e^{2\pi i/3}$ [see also Eq. (73)], which is unique except for trivial $SO(3)_I$ and $U(1)_\varphi$ rotations. In the absence of magnetic field, the quasiparticle excitation energy consists of two branches $E_\pm(\mathbf{k}) = [h_0(\mathbf{k})^2 + |d(\mathbf{k})|^2 \pm |d(\mathbf{k}) \times d^*(\mathbf{k})|]^{1/2}$, where $E_+(\mathbf{k})$ is full gap and $E_-(\mathbf{k})$ has eight nodal points $\pm \mathbf{k}_{x=1, \dots, 4}$, each of which is a Weyl point. The subscript x denotes the four vertices of a tetrahedron, and $\pm$ represents the monopole charge of the Weyl point. Because of the topological nature of Weyl SCs/SFs, there exist surface zero energy states which connect two oppositely charged Weyl points on the projected momentum space normal to the surface direction.

Ferromagnetic state

For $|\beta_1| - \beta_1 < \beta_3$, the ferromagnetic state described by $A_{\mu i} = \Delta(\hat{u}_\mu + i\hat{v}_\mu)(\hat{u}_i + i\hat{v}_i)$ minimizes the GL functional. This nonunitary state is also unique except for trivial $SO(3)_I$ and $U(1)_\varphi$ rotations. The order parameter is equivalent to the A_1 state of the SF ^3He . The bulk quasiparticle spectrum consists of two parts: one is a normal fluid and the other is a Weyl SF with a pair of oppositely charged Weyl fermions. The ferromagnetic state is also realized in the limit of a strong magnetic field or the vicinity of the critical temperature even in the weak coupling limit owing to the finite-size correction of the Fermi surface.

Magnetized nematic state

Recently, even in the weak coupling limit, nonunitary states are predicted in a magnetic field (Mizushima et al., 2021). As mentioned above, quasiclassical approximation, which treats the size of the Fermi surface as infinity, allows only the nematic states, which is unitary. By contrast, in the presence of the finite-size correction of the Fermi surface, a magnetic field along the $\hat{w}$ -direction induces the nonunitary component into the nematic state with $r \in (-1, -1/2)$ as $A_{\mu i} = \Delta[\hat{u}_\mu \hat{u}_i + r\hat{v}_\mu \hat{v}_i + i\kappa(\hat{u}_\mu \hat{v}_i + \hat{v}_\mu \hat{u}_i) - (1+r)\hat{w}_\mu \hat{w}_i]$ or equivalently

$$A_{\mu i} = \Delta \begin{pmatrix} 1 & i\kappa & 0 \\ i\kappa & r & 0 \\ 0 & 0 & -(1+r) \end{pmatrix}. \quad (93)$$

For simplicity, Mizushima et al. (2021) studied the case of $r = -1$, that is, in a strong magnetic field. In the quasiclassical limit, $\kappa = 0$ and the D_4 -BN state is realized. The order parameter tensor in the angular momentum representation is reduced to $A_{\mu i} = \Delta[\Gamma_2 + \Gamma_{-2}]_{\mu i}$, which shows the same gap amplitudes for $M = \pm 2$. The finite size correction of the Fermi surface induces a finite κ . In the angular momentum representation, the order parameter tensor becomes $A_{\mu i} = \Delta[(1+\kappa)\Gamma_2 + (1-\kappa)\Gamma_{-2}]_{\mu i}$. Thus, κ represents the imbalance between the $M = \pm 2$ sectors. In terms of the gap matrix in the spin basis, the Cooper pairs are decomposed into two spin polarized sectors $|\uparrow\uparrow\rangle$ and $|\downarrow\downarrow\rangle$ with different gap amplitudes. Each spin sector has a polarized orbital angular momentum state, and thus, a pair of the Weyl fermions appears at the north pole and the south pole in each spin sector. The orbital angular momentum between these two spin states is opposite, which means that two Weyl fermions with opposite helicity at each pole. This is in contrast to the A_2 phase proposed for the SF ^3He . In the limit of a strong magnetic field or the vicinity of the critical temperature, $\kappa \rightarrow 1$, the ferromagnetic state is realized. However, we note that this imbalance originates from the finite size effect of the Fermi surface. The effect is parametrized by Δ/ε_F , which is usually small for conventional neutron stars, and thus the imbalance κ is also expected to be small.

Vortices in 3P_2 SFs

The vortices admitted in 3P_2 SFs are basically the same as those in spin-2 BECs, which are discussed in Section “Examples of non-Abelian vortices.” Table 4 summarizes remaining symmetry, order parameter manifold, and fundamental group of the topological defects of the above-discussed possible phases. Non-Abelian vortex anyons are included in the D_2 - and D_4 -BN states and the cyclic state as discussed in Section “Fusion rules for non-Abelian vortex anyons.” Non-Abelian vortex anyons in the D_2 -BN states are spin vortices of π rotation, as shown in Eq. (81). The D_4 -BN states admit HQVs (V)–(VII) in Eq. (72) in addition to spin vortices (III) and

⁵Here we use the bar to distinguish the magnetic π -rotation about the x -axis introduced later.

Table 4 Summary of order parameters (r, κ in Eq. (93)), remaining symmetry (H), ($R \simeq G/H$), and topological vortices $\pi_1(R)$ in possible phases.

Phase	r & κ in Eq. (93)	H	$R \simeq G/H$	$\pi_1(R)$
UN	$r = -1/2$ & $\kappa = 0$	$D_\infty \simeq O(2)$	$U(1) \times \mathbb{R}P^2$	$\mathbb{Z} \oplus \mathbb{Z}_2$
D_2 -BN	$r \in (-1, -1/2)$ & $\kappa = 0$	D_2	$[U(1) \times SO(3)]/D_4$	$\mathbb{Z} \oplus \mathbb{Q}$
D_4 -BN	$r = -1$ & $\kappa = 0$	D_4	$[U(1) \times SO(3)]/D_4$	$\mathbb{Z} \times_h D_4^*$
Cyclic	$r = e^{2\pi i/3}$ & $\kappa = 0$	T	$[U(1) \times SO(3)]/T$	$\mathbb{Z} \times_h T^*$
Mag. D_2 -BN	$r \in (-1, -1/2)$ & $\kappa \in (0, 1)$	0	$U(1) \times SO(3)$	$\mathbb{Z} \oplus \mathbb{Z}_2$

(IV) in Eq. (72) as non-Abelian vortex anyons (see also Table 3). The cyclic states admit 1/3-quantum vortices (IV)–(VII) in Eq. (77) as well as spin vortices (III) in Eq. (77) as non-Abelian vortex anyons (see also Table 2).

Especially, the non-Abelian vortex in the D_4 -BN state is the main target in the remaining part. We explain the vortices in the D_4 -BN state in the beginning of the next subsection.

Half quantum vortex in D_4 -BN state

Vortices in D_4 -BN state

The D_4 -BN state, which can be thermodynamically stabilized by a large magnetic field, has a pair of point nodes at the north and south poles along the direction of the magnetic field (Masuda and Nitta, 2016; Mizushima et al., 2017; Yasui et al., 2019b; Mizushima et al., 2020). Hereafter, we focus on the D_4 -BN state with a pair of point node along $\hat{w} = \hat{z}$. The homogeneous order parameter tensor has a diagonal form (Sauls and Serene, 1978): $A = \Delta \text{diag}(1, -1, 0)$ (Eq. 68), which is invariant under a D_4 group. (A similar order parameter form is taken in the planar state of SF ^3He (Makhlin et al., 2014; Silaev and Volovik, 2014), but different topological defects are resulted from different order parameter manifolds.)

As already discussed in Section “Non-Abelian vortex anyons,” the order parameter manifold in the D_4 -BN state is then characterized by the broken symmetry, $R \simeq [U(1) \times SO(3)]/D_4$, see Eq. (69). The topological charges of line defects are characterized by the first homotopy group, Eq. (75)

$$\pi_1(R) \simeq \mathbb{Z} \times_h D_4^* \quad (94)$$

where $\times_h$ denotes a product defined in Kobayashi et al. (2012). This ensures two different classes of topological line defects: Vortices with commutative topological charges and vortices with noncommutative topological charges. The former includes integer vortices (I) in Eq. (72) with or without internal structures, while an example of the latter is the non-Abelian HQV, (V)–(VII) in Eq. (72). Integer vortices are characterized by vorticity quantized to an integer number because of the singlevaluedness of the order parameter. Fractionally quantized case such as a HQV usually has a phase jump (π -phase jump for a HQV) along the contour surrounding the vortex. In the D_4 -BN state, however, the phase discontinuity is compensated by the phase originating from the discrete rotation of the D_4 symmetry. Thereby HQVs are topologically allowed. Here, we particularly focus on the case where the vorticity is along the $\hat{z}$ -direction accompanying the π -phase jump compensated by the C_4 rotation about the $\hat{z}$ -axis, as indicated in Figs. 8B, 10A and F, and 11A. Such HQVs belong to the group (V) or (VI) in Eq. (72).

Hereafter, we review possible vortices when the vorticity and the point nodes of the D_4 -BN state are along the $\hat{z}$ -direction. As a basis set of the order parameter tensor $A_{\mu i}$, the eigenstates of the z component of the total angular momentum, denoted by $J_z \Gamma_M = M \Gamma_M$, are convenient: $A_{\mu i}(\rho, \theta) = \sum_{M=-2}^2 \gamma_M(\rho, \theta) [\Gamma_M]_{\mu i}$, where the cylindrical coordinate system $\mathbf{R} = (\rho, \theta)$ is introduced with assumption of uniformity along the z -direction. In the region far from the vortex core $\rho \rightarrow \infty$, there is no radial dependence, and the order parameter modulation is described by the $U(1)$ phase rotation characterized by vorticity κ and the simultaneous rotation in the spin-orbit space of Cooper pairs. For the latter rotation by angle φ about the $\hat{z}$ -axis, the other components of the triad, $\hat{x}$, and $\hat{y}$, are transformed as

$$R(\varphi) : \hat{x} \rightarrow \cos \varphi \hat{x} + \sin \varphi \hat{y}, \quad (95)$$

$$R(\varphi) : \hat{y} \rightarrow -\sin \varphi \hat{x} + \cos \varphi \hat{y}. \quad (96)$$

Using Γ_M , the $U(1)$ phase winding and the spin-orbit rotation for nonzero bulk components (i.e., $\rho \rightarrow \infty$) are expressed as

$$A_{\mu i}(\theta) = \sum_{M=-2}^2 \gamma_{M,\infty} e^{i\kappa\theta - M\varphi} [\Gamma_M]_{\mu i} \equiv \sum_{M=-2}^2 \gamma_{M,\infty} e^{i(\kappa - nM)\theta} [\Gamma_M]_{\mu i}. \quad (97)$$

Table 5 Internal structures of axisymmetric vortices. The second and third columns show order parameters of the core structure. The fourth column is coreless (singular) whether the vortex core is occupied (unoccupied) by some SF components. The last column accounts for the preserved symmetry.

Vortex	$\gamma_{M=0}(\rho)$	$\gamma_{M=\pm 1}(\rho)$	Core	Symmetry
<i>o</i> vortex	Real	Zero	Singular	P_1, P_2, P_3
<i>u</i> vortex	Complex	Zero	Singular	P_1
<i>v</i> vortex	Real	Real	Coreless	P_2
<i>w</i> vortex	Real	Imaginary	Coreless	P_3
<i>uvw</i> vortex	Complex	Complex	Coreless	—

Especially, in the D_4 -BN state with the point nodes along the $\hat{z}$ -axis, $|\gamma_{2,\infty}| = |\gamma_{-2,\infty}|$ and $\gamma_{\pm 1,\infty} = \gamma_{0,\infty} = 0$. Here in the second line, we parametrize $\varphi = n\theta$ along the contour surrounding the vortex, where the spin-orbit rotation can be regarded as the n -fold J -disgyration.⁶ Note that n is not necessarily an integer. The boundary condition of a vortex characterized by (κ, n) is given by Eq. (97).

Axisymmetric singly quantized vortex

The integer vortices belong to a class $\kappa \in \mathbb{Z}$. Even in the singly quantized case $\kappa = \pm 1$, however, there are many possibilities because of differences in the internal structure and the disgyration in the spin-orbit space. As a simple case, the axisymmetric vortex can be described as $A_{\mu i}(\rho, \theta) = \sum_{M=-2}^2 \gamma_M(\rho) e^{i(\kappa-M)\theta} [\Gamma_M]_{\mu i}$ in a whole region, which includes complex radial functions $\gamma_M(\rho)$ to be determined. The disgyration of the axisymmetric vortex is one-fold ($n = 1$ in Eq. 97), that is, the 2π rotation of the triad around the vortex. Thus, the axisymmetric vortex belongs to the conjugacy class (II) in Eq. (72).⁷ Although the loss in the kinetic energy becomes large because of the J -disgyration, there is a nice analogy with vortices in SF $^3\text{He-B}$ phase. As in the SF $^3\text{He-B}$ phase, the symmetry of the vortices can be characterized by three discrete symmetries called $P_{1,2,3}$ symmetries (Salomaa and Volovik, 1985b, 1987), which are discussed in the next subsection.⁸ The internal structures $\gamma_{-1,0,1}(\rho)$ characterize a classification based on these discrete symmetries, which allows several vortices as summarized in Table 5. Within an axisymmetric condition, only *o* vortex or *v* vortex is realized as a self-consistent solution. The *o* vortex has a singular core and is the most symmetric one so that it meets all the discrete symmetries. By contrast, the core of the axisymmetric *v* vortex is occupied by the SF component $\gamma_{\pm 1}$ for $\kappa = \pm 1$, and it has the P_2 (magnetic mirror reflection) symmetry, but does not have the P_1 (inversion) or P_3 (magnetic π -rotation about the x -axis) symmetries. Energetically, the *v* vortex is more stable than the *o* vortex because of a gain in the condensation energy in the core region. However, the induced component of the *v* vortex which occupies the core is suppressed by a magnetic field.

Nonaxisymmetric singly quantized vortex

Without the axisymmetric condition, the lower energy condition for a singly quantized vortex is given by $(\kappa, n) = (\pm 1, 0)$ to reduce the loss of the gradient energy. Such a vortex belongs to the conjugacy class (I) in Eq. (72). In this case, so-called double-core vortex (*d* vortex) can be a self-consistent solution (Masaki et al., 2022) as in the SF $^3\text{He-B}$ phase (Thuneberg, 1986; Salomaa and Volovik, 1986). The *d* vortex is also called the nonaxisymmetric *v* vortex because it has the P_2 symmetry but does not have the P_1 and P_3 symmetries (Tsutsumi et al., 2015). Note that the axial symmetry is spontaneously broken for the *d* vortex in the SF $^3\text{He-B}$ phase, while the symmetry is broken by the boundary condition for the *d* vortex in a 3P_2 SF. Fig. 9 shows the order parameter structure of the *d* vortex in the D_4 -BN state for $T = 0.4T_c$ and $B = 0.5T_c$ with critical temperature T_c . In the panels, the unit of length is the coherence length defined by $\xi_0 = v_F/2\pi T_c$ with Fermi velocity v_F , where $\langle \dots \rangle_F$ accounts for the Fermi surface average. The bulk components $\gamma_{\pm 2}$ have a conventional vortex structure with a single phase winding [see panels (A) and (B)]. The double core structure can be clearly observed in the total amplitude defined by $\left[\frac{3}{2} \text{Tr}(\hat{\Delta}^\dagger \hat{\Delta})_F \right]^{1/2}$ in panel (F). Such a structure is due to the occupations of the core by $\gamma_{M=\pm 1}$ as shown in panels (C) and (D). As can be seen below, the *d* vortex is not the lowest energy state among the vortex states with $(\kappa, n) = (\pm 1, 0)$ in the D_4 -BN state and it splits into two HQVs. The *d* vortex in the SF $^3\text{He-B}$ phase is the most stable vortex solution in the low pressure region (Kasamatsu et al., 2019; Regan et al., 2019). A *d* vortex is realized as the lowest energy state in the UN and the D_2 -BN states.

HQVs

The HQVs can be characterized by $\kappa = \pm 1/2$. The possibility of the half-quantized vortex in the D_4 -BN state was pointed out long back in 1980 (Sauls, 1980) on the basis of the topological consideration of the form of $A_{\mu i}$. Since κ is a half odd integer, the $U(1)$ phase part gives the minus sign under the spatial rotation $\theta \rightarrow \theta + 2\pi$. By rotating the triad by angle $\pm \pi/2$ while going around the vortex, which is denoted by $n = \pm 1/4$ in Eq. (97), the above minus sign can be compensated by the other minus sign stemming from the disgyration. This topological consideration is represented by the boundary condition Eq. (97) with $(\kappa, n) = (\pm 1/2, \pm 1/4)$, which

⁶The term “ J -disgyration” accounts for a singularity in the spin-orbit space, that is, the total angular momentum (J) space. Spin disgyrations and orbital disgyrations are introduced after Eq. (32).

⁷In Section “Examples of non-Abelian vortices,” we discuss the spin vortex of 2π rotation in spin-2 BECs.

⁸The P_3 symmetry is already introduced when defining the one-dimensional winding number in the bulk nematic state.

Fig. 9 Gap structure of the d -vortex in the D_4 -BN state ($T = 0.4T_c$ and $B = 0.5T_d$). (A)–(E) Amplitude of each angular momentum sector. Red arrows indicate the phase winding structures. (F) Total amplitude of the order parameter defined by $\left[\frac{3}{2}\text{Tr}(\hat{\Delta}^\dagger \hat{\Delta})_F\right]^{1/2}$.

Fig. 10 HQV with $(\kappa, n) = (1/2, +1/4)$ [(A)–(E)] and $(\kappa, n) = (1/2, -1/4)$ [(F)–(J)]. The boundary conditions are sketched in (A) and (F). The amplitudes of γ_M for $M = -2$ and 0 (+2 and 0) are shown in (B) and (D) [(G) and (I)], respectively. The phases of γ_M for $M = -2$ and 0 (+2 and 0) are shown in (C) and (E) [(H) and (J)], respectively. Adapted from Masaki Y, Mizushima T, and Nitta M (2022) Non-Abelian half-quantum vortices in 3P_2 topological superfluids. Physical Review B 105 (22): L220503. ISSN 2469-9950. <https://doi.org/10.1103/PhysRevB.105.L220503>. ©2022 American Physical Society.

belongs to the conjugacy class (V) or (VI) in Eq. (72). The gradient energy of an isolated HQV far from the core is a half of that of an singly quantized vortex described by $(\kappa, n) = (\pm 1, 0)$, namely, the energy of two HQVs is the same as that of the singly quantized vortex except for contributions from the vortex cores. In other words, whether the singly quantized vortex can be split into two HQVs depends on the energy of their internal structures and the interaction energy between two HQVs.

Fig. 11 (A) Schematic image of a molecule of non-Abelian HQVs in a D_4 -BN state at a cross section perpendicular to the two parallel vortex lines, characterized by $(\kappa, n) = (1/2, +1/4)$ at $x = d_v/2$ and $(1/2, -1/4)$ at $x = -d_v/2$. Its spin-momentum structure is shown by objects with *color arrows* representing d vectors. The *color map* on the surface shows the $U(1)$ phase, and the bottom plot shows the induced component also shown in panel (C-1). (B) Interaction energy of two HQVs as a function of their separation d_v . The inset shows the total amplitude of the order parameter for the HQV molecule whose intervortex distance is indicated by the *arrow*. The free energy is scaled as $\bar{J}_{\text{sn}} = J_{\text{sn}} / (v_n T_c^2 \xi_0^2 \Omega_z)$, where Ω_z is the length of the system in the z direction, and v_n is the density of states at the Fermi energy in the normal state. The energy at $d_v = 0$ is the free energy of the d vortex shown in Fig. 9. (C-1) and (C-2) The amplitude and the phase of the induced component γ_0 . The intervortex distance d_v is the same as that in the inset of panel (B). Adapted from Masaki Y, Mizushima T, and Nitta M (2022) Non-Abelian half-quantum vortices in 3P_2 topological superfluids. *Physical Review B* 105 (22): L220503. ISSN 2469-9950. <https://doi.org/10.1103/PhysRevB.105.L220503>. ©2022 American Physical Society.

Although the above topological consideration does not take into account the core structure, recently, the whole structures of isolated HQVs were studied using the phenomenological GL theory (Masuda and Nitta, 2020; Kobayashi and Nitta, 2022a, b) and the microscopic quasiclassical theory (Masaki et al., 2022). It is proposed that an integer vortex with $\kappa = 1$ can split into two HQVs with $(\kappa, n) = (1/2, 1/4)$ and $(\kappa, n) = (1/2, -1/4)$ (Masuda and Nitta, 2020). Here we assume that $\kappa > 0$ without loss of generality. The configuration of the two HQVs given as one for $n_1 = +1/4$ with its core at R_1 and the other for $n_2 = -1/4$ with its core at R_2 has the following boundary condition at R :

$$A(\mathbf{R}) \sim \sum_{M=\pm 2} e^{i(\kappa-n_1M)\theta_1 + i(\kappa-n_2M)\theta_2} \gamma_M \Gamma_M, \quad (98)$$

where θ_1 (θ_2) is the angle of $\mathbf{R} - \mathbf{R}_1$ ($\mathbf{R} - \mathbf{R}_2$). Since the difference between θ_1 and θ_2 is negligible for $|\mathbf{R}| \rightarrow \infty$, the phase part behaves as $\exp(2i\kappa\theta)$ [$\theta \simeq (\theta_1 + \theta_2)/2$], which means the boundary conditions for the two HQVs and the singly quantized vortex are equivalent in the limit $\rho \rightarrow \infty$. In the following, we explain the internal structure of each HQV, and the interaction energy of the two HQV vortex through the comparison of the singly quantized vortex (Masaki et al., 2022). Particularly, the nonaxisymmetric internal structure of each HQV is important to the interaction energy.

Isolated HQV $(\kappa, n) = (1/2, +1/4)$

The two disgyrations of the triads, given by $n = \pm 1/4$, are inequivalent because one is parallel to the vorticity while the other is antiparallel. Here we first explain the antiparallel case $(n, \kappa) = (1/2, 1/4)$. In the above notation, by setting $\mathbf{R}_1 = (0, 0)$ and $\mathbf{R}_2 = (-\infty, 0)$, and thus setting $\theta_2 \rightarrow 0$, the boundary condition is obtained from Eq. (98). In this case, the relative phase of $\gamma_{\pm 2}$ is zero, and the schematic image of the disgyration is drawn in Fig. 10A. Each circular object shows the directions of d -vectors by *colored arrows*, whose color bar is the same as in panel (C). There are also the *cyan* and *magenta lines*, which represent the directions of the eigenvalues $+1$ and -1 of the order parameter A , respectively. This HQV is $(1/2, C_4)$ in the conjugacy class (V) in Eq. (72). The self-consistent solutions of the nontrivial components are shown in panels (B)–(E). Here γ_2 , not shown, is almost uniform without phase winding, as expected from the boundary condition $\kappa - n_1 M = 1/2 - 1/4 \times 2 = 0$. The other bulk component γ_{-2} is a conventional singular vortex with the single-phase winding shown in panel (C). The amplitude and the phase of the internal structure of γ_0 are, respectively, shown in panels (D) and (E). The phase of the internal structure is oppositely winding against γ_{-2} , which can be understood by analogy with a vortex in a spinless chiral p -wave SC. We assume, for simplicity, $\bar{k}_z = 0$, and then write $\bar{k}_\chi = (k_x + i\chi k_y)/k_F = e^{i\chi\alpha}$ with the sign of the angular momentum $\chi = \pm$. With this notation, the gap function is written as

$$\hat{\Delta}(\mathbf{k}_F, \mathbf{R}) = [-\gamma_2(\mathbf{R})\bar{k}_+ + \gamma_0(\mathbf{R})/\sqrt{6}\bar{k}_-][\uparrow\uparrow] + [\gamma_{-2}(\mathbf{R})\bar{k}_- - \gamma_0(\mathbf{R})/\sqrt{6}\bar{k}_+][\downarrow\downarrow]. \quad (99)$$

In each spin sector, two opposite orbital-angular-momenta, $\bar{k}_{\pm}$, are mixed owing to the induced component γ_0 . In a spinless chiral p -wave SC, the induced component has the opposite angular momentum relative to the component which has a nonzero order parameter far from the vortex core, that is, $\chi_i = -\chi_b$ (Heeb and Agterberg, 1999; Matsumoto and Heeb, 2001). Here we call the latter component the *bulk component*, and χ_b (χ_i) represents the sign of the angular momentum for the bulk (induced) component. The vorticity of the induced component, κ_i , is given by $\kappa_i = \kappa_b + \chi_b - \chi_i$, where κ_b is the vorticity of the bulk component. Here the $\chi_b - \chi_i$ accounts for the angular momentum difference between the bulk and induced components, and is reduced to $2\chi_b$. For the $(1/2, +1/4)$ -HQV, the bulk component γ_{-2} has the vorticity $\kappa_b = \kappa - n(-2) = 1$, and $\chi_b = -1$. Thereby $\kappa_i = \kappa_b + 2\chi_b = -1$ successfully explains the vorticity of the induced component shown in panel (E). More striking feature is the three-fold symmetry in the amplitude of the induced component $|\gamma_0|$. Reflecting this discrete symmetry, the phase evolution of the induced component surrounding the vortex is nonlinear. As seen from Eq. (99), the main structure of this HQV is in the spin-down sector.

Isolated HQV (κ, n) = (1/2, -1/4)

The other HQV, characterized by $(1/2, -1/4)$, at $\mathbf{R}_2 = (0, 0)$, is obtained by $\mathbf{R}_1 \rightarrow (+\infty, 0)$, that is, $\theta \rightarrow \pi$ in Eq. (98), in which the relative phase of $\gamma_{\pm 2}$ is opposite because of the phase factor $\exp[i(1/2 + M/4)\pi]$ from the $(1/2, +1/4)$ HQV. This HQV is $(1/2, C_4^{-1})$ in the conjugacy class (V) in Eq. (72), and its disgyration is schematically drawn in Fig. 10F. In contrast to the previous case, a conventional vortex structure appears in the $M = +2$ sector shown in panels (G) and (H), while an almost uniform structure without phase winding is in the $M = -2$ sector. In panel (J) the phase winding of the induced component is $+3$, which can be understood as in the previous case: $\kappa_i = \kappa_b + 2\chi_b = 3$ for $\kappa_b = \kappa + M/4 = 1$ and $\chi_b = +1$. The phase evolution surrounding the vortex is again nonlinear reflecting the discrete symmetry of the amplitude $|\gamma_0|$, which is fivefold as shown in panel (H). The major vortex structure of this HQV is in the spin-up sector.

Molecule of HQVs (stability)

The two types of internal structures in the $M = 0$ component induced for the HQVs with $n = \pm 1/4$ are modulated by the connection of these two HQVs. This modulation causes an interaction between the two HQVs. The interaction energy of the two HQVs is defined by $\Delta\mathcal{J}_{\text{sn}}(d_v) = \mathcal{J}_{\text{sn}}(\mathbf{R}_1, \mathbf{R}_2) - \mathcal{J}_{\text{sn}}^+(\mathbf{R}_1) - \mathcal{J}_{\text{sn}}^-(\mathbf{R}_2)$ based on the Luttinger–Ward energy functional $\mathcal{J}_{\text{sn}}$ (Vorontsov and Sauls, 2003). Here the two HQVs are at $\mathbf{R}_1 = (d_v/2, 0)$ and $\mathbf{R}_2 = (-d_v/2, 0)$, schematically shown in Fig. 11A, whose energy is denoted by $\mathcal{J}_{\text{sn}}(\mathbf{R}_1, \mathbf{R}_2)$. The energies of the isolated HQVs (κ, n) = $(1/2, +1/4)$ at $\mathbf{R}_1$ and $(1/2, -1/4)$ at $\mathbf{R}_2$ are denoted by $\mathcal{J}_{\text{sn}}^+(\mathbf{R}_1)$ and $\mathcal{J}_{\text{sn}}^-(\mathbf{R}_2)$, respectively.

Fig. 11B shows the interaction energies of the two HQVs as a function of intervortex distance d_v . When $d_v = 0$, the d vortex (the singly quantized vortex with double core structure) is realized. The gap structure is shown in Fig. 9. Importantly, the positive energy of the d vortex means that two isolated HQVs ($d_v \rightarrow \infty$) are more stable than the d vortex. The actual interaction energy takes the minimum at finite d_v , indicating the instability of the d vortex into a bound state of the two HQVs like a molecule. As discussed in Section “Examples of non-Abelian vortices,” a singly quantized vortex (κ, n) = $(1, 0)$ in the conjugacy class (I) in Eq. (72) splits into two HQVs $(1/2, +1/4)$ and $(1/2, -1/4)$ in the class (V).

The stabilization mechanism in this molecule state is a deformation in the nonaxisymmetric-induced component γ_0 , as shown in Fig. 11C-1 and C-2, realized in the strongly spin–orbit-coupled Cooper pairs (Masaki et al., 2022). This mechanism is purely intrinsic and possible even in the weak coupling limit, different from those in other systems such as the SF ^3He (Salomaa and Volovik, 1985a) and unconventional SCs (Chung et al., 2007): In the SF ^3He -A phase, Volovik and Salomaa phenomenologically introduced some corrections in spin mass to stabilize the HQV (Salomaa and Volovik, 1985a); This correction might be regarded as a kind of strong coupling effect through the Fermi liquid correction, but another strong coupling effect is known to destabilize the HQV (Kawakami et al., 2009, 2010, 2011; Mizushima et al., 2016). Vakaryuk and Leggett unveiled that the HQVs in equal spin pairing states, such as ^3He -A and D_4 -BN, are accompanied by a nonzero spin polarization even in the absence of external Zeeman coupling (Vakaryuk and Leggett, 2009). The coupling of such spin polarization to external magnetic fields may affect the stability of HQVs. Another example of the stabilization mechanism is an extrinsic one in the polar and polar-distorted phases of the SF ^3He because of strongly anisotropic impurities, as discussed in Section “Platforms for Majorana zero modes.”

Non-Abelian anyon in non-Abelian vortex

In this section, first the zero energy-bound states in above-discussed HQVs are demonstrated. Second we summarize the discrete symmetries in the presence of vortices, and finally discuss the topological protection of the zero energy states and their non-Abelian nature.

Existence of zero energy states

To investigate fermionic bound states at discrete energy levels, it is necessary to solve the BdG Eq. (92). By assuming the spatial uniformity along the z -direction, the quantum number is labeled as $v = (\alpha, k_z)$, and only the $k_z = 0$ sector is focused on to seek for zero energy bound states. The direct numerical calculation gives us a spectral function including the discrete bound states around the HQV-cores, as shown in Fig. 12A. There are two zero energy states localized in both of the cores. Here, the molecule state of the

Fig. 12 Local density of states $v_{k_z=0}(\mathbf{R}; \omega)$ at $k_z = 0$ and $y = 0$ for a pair of HQVs located at $(x, y) = (\pm d_v/2, 0)$ with $d_v \simeq 10.7\xi_0$. The spatial distributions of the two zero energy states are different. Adapted from Masaki Y, Mizushima T, and Nitta M (2022) Non-Abelian half-quantum vortices in 3P_2 topological superfluids. Physical Review B 105 (22): L220503. ISSN 2469-9950. <https://doi.org/10.1103/PhysRevB.105.L220503>. ©2022 American Physical Society.

two HQVs with $d_v \simeq 10.7\xi_0$ is used for a gap function in the BdG equation, and the spectral function, also known as the local density of state, is defined as $v_{k_z=0}(\mathbf{R}; \omega) = \sum_{\alpha, \sigma} |u_{\alpha, k_z=0, \sigma}(\mathbf{R})|^2 \delta(\omega - \epsilon_{\alpha, k_z=0})$ along $\mathbf{R} = (x, 0)$, where $u_{\alpha, k_z, \sigma}(\mathbf{R})$ is the particle component with spin σ of the eigenfunction $\vec{u}_{\alpha, k_z}(\mathbf{R})$. In the calculation, the parameter $k_F \xi_0$, characterizing the discreteness of the bound states, is set to 5. The Majorana condition, $u_{\alpha, k_z=0, \sigma}(\mathbf{R}) = [v_{\alpha, k_z=0, \sigma}(\mathbf{R})]^*$, for the wave functions of the zero energy state can be confirmed (Masaki et al., 2022).

Discrete symmetry of vortices

We utilize the semiclassical approximation to clarify the symmetry and topology of vortices, following Tsutsumi et al. (2015), Mizushima et al. (2016), and Shiozaki and Sato (2014). In the semiclassical approximation, the spatial modulation due to a vortex line is treated as adiabatic changes as a function of the real-space coordinate surrounding the defect with the angle θ . Then, the BdG Hamiltonian in the base space, $(\mathbf{k}, \theta)$, is obtained from Eq. (92) as

$$\tilde{\mathcal{H}}(\mathbf{k}, \theta) = \begin{pmatrix} \hat{h}_N(\mathbf{k}) & \hat{\Delta}(\mathbf{k}, \theta) \\ \hat{\Delta}^\dagger(\mathbf{k}, \theta) & -\hat{h}_N^*(\mathbf{k}) \end{pmatrix}, \quad (100)$$

where the 3P_2 pair potential within a semiclassical approximation is given by

$$\hat{\Delta}(\mathbf{k}, \theta) = i\hat{\sigma}_\mu A_{\mu i}(\theta) k_i / k_F \hat{\sigma}_\gamma. \quad (101)$$

Let us now summarize the discrete symmetries of the BdG Hamiltonian in Eq. (100). In the presence of vortex, the BdG Hamiltonian breaks the time-reversal symmetry $\hat{T} = -i\hat{\sigma}_y K$, but holds the particle-hole symmetry

$$\check{C}\tilde{\mathcal{H}}(\mathbf{k}, \theta)\check{C}^{-1} = -\tilde{\mathcal{H}}(-\mathbf{k}, \theta), \quad (102)$$

where $\check{C} = \check{c}_K K$ and K is the complex conjugation operator. In addition to the particle-hole symmetry, three discrete symmetries, the $\{P_1, P_2, P_3\}$, are pointed out to be relevant to vortices of the SF $^3\text{He-B}$ phase (Salomaa and Volovik, 1985b, 1987). Their representations are given by

$$\hat{P}_1 = P U_\pi \hat{1}, \quad \hat{P}_3 = \hat{T} \hat{C}_{2,x}, \quad (103)$$

and $\hat{P}_2 = \hat{P}_1 \hat{P}_3$. Here, $P, U_\pi = e^{i(\kappa+1)\pi}$, $\hat{C}_{2,x} = e^{-i\hat{j}_x \pi}$ are the spatial inversion, the discrete phase rotation, and the π -rotation in the spin-orbit space about the x -axis. The physical meanings of P_1, P_2 , and P_3 symmetries are the inversion, magnetic reflection, and magnetic π -rotation symmetries, respectively. From the definition, $P_1 P_2 P_3 = 1$. Under these symmetry operations, a momentum $\mathbf{k}$ and a spin $\boldsymbol{\sigma}$ are transformed as

$$P_1 : \mathbf{k} \rightarrow (-k_x, -k_y, -k_z), \quad \boldsymbol{\sigma} \rightarrow (\sigma_x, \sigma_y, \sigma_z), \quad (104)$$

$$P_2 : \mathbf{k} \rightarrow (k_x, -k_y, -k_z), \quad \boldsymbol{\sigma} \rightarrow (-\sigma_x, \sigma_y, \sigma_z), \quad (105)$$

$$P_3 : \mathbf{k} \rightarrow (-k_x, k_y, k_z), \quad \boldsymbol{\sigma} \rightarrow (-\sigma_x, \sigma_y, \sigma_z). \quad (106)$$

Under these transformation, the order parameters are transformed as

$$P_1 : \gamma_M(\rho, \theta) \rightarrow -\gamma_M(\rho, \theta + \pi), \quad (107)$$

$$P_2 : \gamma_M(\rho, \theta) \rightarrow (-1)^{\kappa+M} [\gamma_M(\rho, \pi - \theta)]^*, \quad (108)$$

$$P_3 : \gamma_M(\rho, \theta) \rightarrow (-1)^M [\gamma_M(\rho, -\theta)]^*. \quad (109)$$

For axisymmetric vortices, we confirm the nonzero components of $\gamma_M(\rho)$ summarized in Table 5 by using the relation $\gamma_M(\rho, \theta) = \gamma_M(\rho) e^{i(\kappa-M)\theta}$. For example, $P_2 : \gamma_M(\rho) e^{i(\kappa-M)\theta} \rightarrow \gamma_M^*(\rho) e^{i(\kappa-M)\theta}$, and when the P_2 symmetry is preserved, $\gamma_M(\rho) = \gamma_M^*(\rho)$ can be obtained. In the case of the d vortex, the P_3 symmetry is broken because of the nonzero $\gamma_{\pm 1}$ components, and the P_2 symmetry is the only preserved symmetry among these three. In the case of isolated HQVs, even though $\gamma_{\pm 1} = 0$, because of the threefold, and fivefold symmetry in the gap amplitude of γ_0 , the P_1 and P_2 symmetries are broken, but the P_3 symmetry is preserved.

Another discrete symmetry is the mirror reflection symmetry about the plane perpendicular to the vortex line, that is, the xy -plane, which is already discussed in Section “Symmetry-protected non-Abelian anyons.” The mirror reflection symmetry M_{xy} transforms the momentum and the spin as

$$M_{xy} : \mathbf{k} \rightarrow (k_x, k_y, -k_z), \quad \boldsymbol{\sigma} \rightarrow (-\sigma_x, -\sigma_y, \sigma_z), \quad (110)$$

and thus the order parameter is transformed as

$$M_{xy} : \gamma_M(\rho, \theta) \rightarrow (-1)^{M+1} \gamma_M(\rho, \theta). \quad (111)$$

Therefore, in the presence of M_{xy} , even M and odd M cannot be mixed. In the case of the D_4 -BN state with the point nodes along the z -direction, $\gamma_{M=\pm 2} \neq 0$, and the only possible mirror operation that commutes with the BdG Hamiltonian at the mirror invariant momentum $\mathbf{k}_M = (k_x, k_y, 0)$ is $\eta = -$ in Eq. (38) when $\gamma_{\pm 1} = 0$. The above-discussed vortices of a 3P_2 SF which preserve the M_{xy} symmetry, are the axisymmetric o and u vortices, and the HQVs.

Topology of the vortex-bound states

On the basis of the above-discussed discrete symmetries, the zero energy state of each HQV is shown to be protected by two topological numbers: one based on the chiral symmetry, a combined symmetry between the particle-hole symmetry and the P_3 symmetry, and the other based on the mirror reflection symmetry.

When the P_3 symmetry is preserved, the semiclassical BdG Hamiltonian is transformed under the combined symmetry operation $\Gamma = CP_3$ with $\Gamma^2 = +1$ as

$$\tilde{\Gamma} \tilde{\mathcal{H}}(\mathbf{k}, \theta) \tilde{\Gamma}^{-1} = \tilde{\mathcal{H}}(k_x, -k_y, -k_z, -\theta). \quad (112)$$

Particularly, for $k_y = k_z = 0$ and $\theta = 0$ or π , the BdG Hamiltonian anticommutes with Γ , which can be regarded as chiral symmetry (Sato et al., 2011; Mizushima et al., 2012; Tsutsumi et al., 2013; Shiozaki and Sato, 2014; Tsutsumi et al., 2015; Masaki et al., 2020; Mizushima et al., 2016). As in the bulk nematic state, as long as the chiral symmetry is preserved, one can define the one-dimensional winding number for $\mathbf{k}_x = (k_x, 0, 0)$ and $\theta = 0$ or π as

$$w_{1d}(\theta) = -\frac{1}{4\pi i} \int dk_x \text{tr} \left[\tilde{\Gamma} \tilde{\mathcal{H}}^{-1}(\mathbf{k}_x, \theta) \partial_{k_x} \tilde{\mathcal{H}}(\mathbf{k}_x, \theta) \right]. \quad (113)$$

The vortices that preserve the P_3 symmetry are o and w vortices, and the non-Abelian HQVs. Among them, the winding numbers ($w_{1d}(0), w_{1d}(\pi)$) of o and w vortices are $(2, -2)$, and thus the topological invariant $w_{1d} = (w_{1d}(0) - w_{1d}(\pi))/2 = 2$ ensures the existence of two zero energy states. In the case of non-Abelian HQVs, ($w_{1d}(0), w_{1d}(\pi)$) is $(2, 0)$ for $(\kappa, n) = (1/2, +1/4)$ and $(0, -2)$ for $(1/2, -1/4)$.⁹ In both cases, the topological invariant w_{1d} becomes 1, which ensures the existence of one zero energy state in each HQV core.

Next we explain the topological invariant based on the mirror reflection symmetry M_{xy} . As discussed above, the BdG Hamiltonian $\mathcal{H}(\mathbf{k}_M, \theta)$ for the mirror invariant momentum $\mathbf{k}_M$ commutes with the mirror operator $\tilde{\mathcal{M}}^\eta$ for $\eta = -$ in Eq. (38). Thus, $\mathcal{H}(\mathbf{k}_M, \theta)$ can be block diagonalized with respect to the mirror eigenstates with eigenvalues $\lambda = \pm i$ as

$$\tilde{\mathcal{H}}(\mathbf{k}_M, \theta) = \bigoplus_{\lambda} \tilde{\mathcal{H}}_{\lambda}(\mathbf{k}_M, \theta). \quad (114)$$

Significantly, even for the BdG Hamiltonian in each mirror subsector, $\tilde{\mathcal{H}}_{\lambda}$, the reduced particle-hole symmetry $\tilde{\mathcal{C}}$ is preserved, though it is not for the other mirror symmetry operator $\tilde{\mathcal{M}}^{\eta=+}$. Therefore, $\tilde{\mathcal{H}}_{\lambda}$ belongs to the class D as well as spinless chiral SCs (Schnyder et al., 2008), and the $\mathbb{Z}_2$ invariant, v_{λ} can be constructed in each mirror subsector (Teo and Kane, 2010b; Qi et al., 2008). Nontrivial (odd) value of v_{λ} ensures that the vortex has a single Majorana zero mode which behaves as a non-Abelian (Ising) anyon (Ueno et al., 2013; Sato et al., 2014; Tsutsumi et al., 2013).

The $\mathbb{Z}_2$ invariant v_{λ} is defined on the base space ($S^2 \times S$) composed of the two dimensional mirror invariant momentum space $\mathbf{k}_M$ and the angle in the real space surrounding the vortex θ , and constructed by the dimensional reduction of the second Chern number defined in the four-dimensional base space ($S^3 \times S$) composed of $\mathbf{k}$ and θ . The $\mathbb{Z}_2$ invariant in each mirror subsector is given by the integral of the Chern–Simons form:

⁹The choice of the relative phase between $\gamma_{\pm 2}$ as π by $\theta_1 \rightarrow \pi$ leads to $(w_{1d}(0), w_{1d}(\pi)) = (0, -2)$ rather than $(2, 0)$ for the HQV of $(\kappa, n) = (1/2, -1/4)$.

$$v_\lambda = \left(\frac{i}{\pi}\right)^2 \int_{S^2 \times S^1} \tilde{Q}_{3,\lambda} \mod 2, \quad (115)$$

$$\tilde{Q}_{3,\lambda} = \text{tr}[\tilde{\mathcal{A}}_\lambda \wedge d \tilde{\mathcal{A}}_\lambda + \frac{2}{3} \tilde{\mathcal{A}}_\lambda \wedge \tilde{\mathcal{A}}_\lambda \wedge \tilde{\mathcal{A}}_\lambda]. \quad (116)$$

A non-Abelian Berry connection $\tilde{\mathcal{A}}_\lambda$ is given by

$$i[\tilde{\mathcal{A}}_\lambda]_{nm} = \sum_\alpha \langle \tilde{u}_{\lambda,n}(\mathbf{k}_M, \theta) | \partial_\alpha \tilde{u}_{\lambda,m}(\mathbf{k}_M, \theta) \rangle d\alpha, \quad (117)$$

where α denotes (k_x, k_y, θ) , and $|\tilde{u}_{\lambda,m}(\mathbf{k}_M, \theta)\rangle$ is the m th eigenstate of $\tilde{\mathcal{H}}_\lambda(\mathbf{k}, \theta)$. Within the semiclassical approximation in the D_4 -BN state, the $\mathbb{Z}_2$ invariant is calculated as

$$v_\lambda = \ell_\lambda \kappa_\lambda \mod 2, \quad (118)$$

where ℓ_λ and κ_λ are the first Chern number and the vorticity in the mirror subsector λ . The former characterizes the bulk topology and $\ell_{\lambda=\pm i} = \pm 1$. The latter is given by $\kappa_\lambda = \kappa - nM$ for the bulk component M in the λ subsector. In the case of the isolated HQVs, $(v_{+i}, v_{-i}) = (0, -1) [(+1, 0)]$ for $(\kappa, n) = (1/2, +1/4) [(1/2, -1/4)]$. The two HQVs host Majorana fermions in different mirror sectors, and thus the $\mathbb{Z}_2$ invariant of the molecule state is given by $(v_{+i}, v_{-i}) = (+1, -1)$. The $\mathbb{Z}_2$ invariant of the v vortex has the same one, and the pairwise Majorana fermions are localized at the same core (Masaki et al., 2020).

The zero energy state bound in each HQV core is protected by the two topological invariants based on the mirror reflection symmetry and the chiral symmetry, and it is identified as non-Abelian (Ising) anyon of the Majorana fermion. Therefore, the HQV in the D_4 -BN state has twofold non-Abelian nature: one from the non-Abelian Ising anyon and the other from non-Abelian first homotopy group.

Conclusion

We have presented various types of non-Abelian anyons in topological SCs/SFs and other systems. Non-Abelian anyons are attracting a great attention because of possible applications to topological quantum computations, where quantum computations are realized by braiding of non-Abelian anyons. The simplest non-Abelian anyons are Ising anyons realized by Majorana fermions hosted by vortices (or edges) of topological superconductors, $v = 5/2$ quantum Hall states, spin liquids, and QCD matter. These are, however, insufficient for universal quantum computations. The other anyons that can be used for universal quantum computations are given by Fibonacci anyons, which exist in $v = 12/5$ quantum Hall states. There are also Yang-Lee anyons, which are nonunitary counterparts of Fibonacci anyons. Another class of non-Abelian anyons of the bosonic origin can be given by non-Abelian vortex anyons realized by non-Abelian vortices supported by a non-Abelian first homotopy group. These vortex anyons exist in BN liquid crystals, cholesteric liquid crystals, spin-2 spinor BECs, and QCD matter. There is a unique system simultaneously admitting two kinds of non-Abelian anyons, which is the Majorana fermions (Ising anyons) and non-Abelian vortex anyons. That is 3P_2 SFs, spin-triplet, p -wave pairing of neutrons, expected to exist in neutron star interiors as the largest topological quantum matter in universe.

Abstract

This article provides a concise description of topological superconductors. After reviewing representative examples of fully gapped topological superconductors in various dimensions, we discuss the basic concepts including the symmetry classification scheme of generic fermionic systems and topological classifications. The bulk-boundary correspondence, one of the hallmarks of topological superconductors, is also discussed, addressing disorder and interaction effects.

Key points

- Topological superconductors are quantum phases of matter that cannot continuously be deformed to trivial states of matter, such as a collection of atoms without any interatomic interaction.
- Topological superconductors host exotic Andreev bound states at their boundaries and vortex cores. They are stable against perturbations and disorder. In some cases, the boundary states are zero-energy Majorana modes. The close-knit relation between the bulk topological properties and protected boundary states is called the bulk-boundary correspondence.
- Examples of topological superconductors include one-dimensional topological superconductors (the Kitaev chain), two-dimensional chiral p -wave superconductors, and the B phase of ^3He in three dimensions. Topological superconductors in different dimensions and symmetry classes can be summarized in the periodic table of topological insulators and superconductors.

Introduction

The concept of topology has prevailed in condensed matter physics to date. The quantum Hall effect (both integer and fractional ones) is one of the first examples that made us realize the pivotal role played by topology in many-body quantum physics (Prange and Girvin, 1990). Since then, the topological concepts in condensed matter physics have been developed in great depth and breadth. The list of topological phenomena and topological systems has also been expanding vastly. In particular, the discovery of topological insulators fueled the development of topological condensed matter physics (Hasan and Kane, 2010; Qi and Zhang, 2011; Bernevig and Hughes, 2013).

Topology is a branch of mathematics that deals with properties that do not change under a continuous deformation of objects (which can be large as long as tearing and gluing are avoided). Likewise, quantum phenomena that have a topological origin or that occur within topological phases of matter can be robust against perturbations such as disorder and interactions. Furthermore, topological phenomena in many-body quantum systems are of purely quantum mechanical origin and go beyond what we expect from classical physics.

Topological concepts can be applied to superconductors (and superfluids). In fact, at the mean-field level, topological superconductors can be thought of as a close cousin of (integer) quantum Hall states and topological band insulators. Within the mean-field theory, superconductors are described in terms of (almost noninteracting) fermionic Bogoliubov quasiparticles and bosonic Cooper pairs. From the point of view of quasiparticles, Cooper pairs can be viewed as a nondynamical background. We can

then discuss the band structure of quasiparticles using the Bogoliubov-de Gennes (BdG) Hamiltonian. In the quantum Hall effect and topological insulators, single-particle (Bloch) wave functions below the energy gap have certain topological properties that are characterized by some topological invariants, such as the Chern number (quantized Hall conductivity). Similarly, in topological superconductors, wave functions of fermionic quasiparticles have topological characters. Furthermore, like their nonsuperconducting cousins, topological superconductors support gapless modes at their boundaries. These are Andreev bound states that appear within the superconducting gap.

For certain types of topological superconductors, the Andreev bound states are Majorana fermion modes—one of the reasons why topological superconductors have become the subject of intense research. Majorana fermions are emergent excitations in condensed matter systems and are known for the fact that they are their own antiparticles. While Majorana fermions have appeared in various branches of physics, such as Neutrino physics, the recent surge of interest came from their promise for robust quantum computation. Due to their topological origin, Majorana fermions can be used as stable qubits (Nayak et al., 2008; Alicea, 2012; Beenakker, 2013).

Overview

Some of the defining properties of gapped topological (ground) states are:

- (i) Topological states are not adiabatically connected to trivial states. Here, by trivial states, we mean states that can be written as a product state, which does not have spatial correlations and entanglement, such as a collection of atoms without any interatomic interactions. In other words, in the phase diagram, topological phases are necessarily separated from trivial phases by quantum phase transitions.
- (ii) Topological states are characterized by quantized topological invariants. These topological invariants are often related to quantized responses of topological systems to an external background. For example, for particle number-conserving systems, an external electromagnetic field can be used to detect, for example, the quantized Hall conductivity. It can also take the form of an unoriented spacetime topology that can detect topological phases protected by symmetry that reverses the orientation of spacetime, such as time-reversal symmetry (TRS). Quantized topological invariants should be contrasted with local order parameters that can detect and characterize more conventional phases of matter with (spontaneous) symmetry-breaking.
- (iii) In the presence of a spatial boundary, d -dimensional topological systems necessarily support excitations localized at the boundary. The appearance of these $(d - 1)$ -dimensional boundary states is a direct manifestation of the bulk topological properties (topological invariants). These boundary states are said to be anomalous in the sense that they cannot exist on their own as $(d - 1)$ -dimensional isolated systems, that is, they cannot be realized as $(d - 1)$ -dimensional isolated lattice systems. This close-knit relation between bulk topological properties and anomalous boundary states is called the bulk-boundary correspondence.

As alluded to in (ii), all these can be discussed in the presence of proper symmetry, such as TRS. For example, the adiabatic (dis)continuity of ground states can be discussed in the presence of symmetry. Because of the symmetry, states that are otherwise connected to trivial states can be made nontrivial. We say that these states are symmetry-protected (from being trivial).

We note that while we focused above on fully gapped topological phases, gapless topological states are also possible, and need to be discussed separately. Also, there is the concept of topologically ordered states (phases), examples of which include fractional quantum Hall states (Wen, 2007). While the above descriptions apply to topologically ordered phases, they require further characterizations such as topological ground-state degeneracy and exotic anyonic excitations.

The above descriptions (i–iii) apply to a broad class of topological systems and topological superconductors are no exceptions. To illustrate the concept of topological superconductors, we will discuss three representative examples: one-dimensional topological superconductivity realized in the so-called Kitaev chain, two-dimensional chiral p -wave superconductors, and the three-dimensional topological superconductivity (superfluidity) realized in the B-phase of ^3He . (In the following, we will work with the natural unit $\hbar = c = 1$ unless otherwise stated.)

One-dimensional topological superconductors

First, let us discuss a one-dimensional topological superconductor using the Kitaev chain (Kitaev, 2001). The Kitaev chain is defined by the Hamiltonian

$$\begin{aligned} \hat{H} = & \frac{t}{2} \sum_i \left(\hat{c}_i^\dagger \hat{c}_{i+1} + \hat{c}_{i+1}^\dagger \hat{c}_i \right) - \mu \sum_i \left(\hat{c}_i^\dagger \hat{c}_i - 1/2 \right) \\ & + \frac{1}{2} \sum_i \left(\Delta^* \hat{c}_i^\dagger \hat{c}_{i+1}^\dagger - \Delta \hat{c}_i \hat{c}_{i+1} \right), \end{aligned} \quad (1)$$

where $\hat{c}_i^\dagger$ ($\hat{c}_i$) is a fermion creation (annihilation) operator at site i on the one-dimensional lattice, and t , Δ , and μ are parameters representing hopping amplitude, pairing potential, and chemical potential, respectively. Note that we here consider spinless fermions. This type of BdG Hamiltonian may arise in proximity-induced superconductivity in a quantum wire with strong spin-orbit coupling, and ferromagnetic atomic chains on a superconductor (Lutchyn et al., 2010; Oreg et al., 2010; Nadj-Perge et al., 2014). For simplicity, we set $t = \Delta \in \mathbb{R}$ in the following. The Kitaev chain in momentum space is written as

$$\hat{H} = \frac{1}{2} \sum_k \begin{bmatrix} \hat{c}_k^\dagger & \hat{c}_{-k} \end{bmatrix} \mathcal{H}(k) \begin{bmatrix} \hat{c}_k \\ \hat{c}_{-k}^\dagger \end{bmatrix}, \quad (2)$$

where $\mathcal{H}(k) = (t \cos k - \mu) \tau_3 - t \sin k \tau_2$,

where $k \in [-\pi, \pi)$ is the one-dimensional wave number, and $\tau_{1,2,3}$ are the Pauli matrices acting on the particle-hole space.

From the quasiparticle band structure, $\varepsilon_\pm(k) = \pm \sqrt{(t \cos k - \mu)^2 + t^2 \sin^2 k}$, we see that there are two gapped phases realized in this model, for $\mu > t$ and $\mu < t$. At $\mu = t$, the gap in the quasiparticle band structure closes (quantum phase transition). These two gapped phases are topologically distinct. Namely, there is no adiabatic path connecting these two phases. This can be checked explicitly for the above Hamiltonian. No matter how we change t , Δ , and μ ; there is no way to connect these two phases without going through a quantum phase transition. This turns out to be true even when we consider a more generic class of deformations of the Hamiltonian. This can be argued at least in two ways.

First, we can construct a (bulk) quantized topological invariant. It is given by a Wilson loop of the Berry connection for the lower quasiparticle band,

$$W = \exp \left[i \oint_{-\pi}^{\pi} dk A^-(k) \right]. \quad (3)$$

Here, $A^-(k)$ is the Berry connection constructed from the quasiparticle wave function for the lower band, $\mathcal{H}(k)|u_-(k)\rangle = \varepsilon_-(k)|u_-(k)\rangle$, as $A^-(k) = i \langle u_-(k) | \frac{\partial}{\partial k} | u_-(k) \rangle$. It can be shown that the topological invariant is quantized and takes only two possible values, $W = +1$ and $W = -1$. The quantization follows from the condition

$$\tau_1 \mathcal{H}(-k)^T \tau_1 = -\mathcal{H}(k), \quad (4)$$

that is satisfied for generic BdG Hamiltonians. For the above model, $W = +1$ for $\mu > t$ while $W = -1$ for $\mu < t$. The above formula for the topological invariant can properly be generalized when there are more than one quasiparticle band for negative quasiparticle energy. Also, it can be written in different forms, for example, by using the Pfaffian of the BdG Hamiltonian (Kitaev, 2001; Chiu et al., 2016).

The topological invariant can also be formulated in terms of the fermion number parity of the many-body ground state $|\text{GS}\rangle$; when periodic boundary condition is imposed, $|\text{GS}\rangle$ is fermion number parity odd/even, $\langle \text{GS} | (-1)^{\hat{N}} | \text{GS} \rangle = \mp 1$ when we are in the topological/trivial superconducting phase, respectively. Here, $(-1)^{\hat{N}} = (-1)^{\sum_i \hat{c}_i^\dagger \hat{c}_i}$ is the total fermion number parity operator. This is the quantized response of one-dimensional topological superconductors to the twisted boundary condition.

Second, in the presence of boundaries (open boundary condition), the topological superconducting phase supports Majorana fermion modes localized at the boundaries. These states appear within the bulk quasiparticle energy gap, and are exactly at zero energy (in the limit where the ratio between the bulk correlation length and the system size goes to zero). To see this, let us introduce Majorana fermion operators as

$$\hat{\lambda}_j := \hat{c}_j^\dagger + \hat{c}_j, \quad \hat{\lambda}'_j := (\hat{c}_j - \hat{c}_j^\dagger)/i, \quad (5)$$

which correspond to the “real” and “imaginary” parts of the complex fermion operators $\hat{c}_j$ and $\hat{c}_j^\dagger$. They satisfy $\{\hat{\lambda}_j, \hat{\lambda}_k\} = \{\hat{\lambda}'_j, \hat{\lambda}'_k\} = 2\delta_{jk}$, $\{\hat{\lambda}_j, \hat{\lambda}'_k\} = 0$. In particular, $(\hat{\lambda}_j)^2 = (\hat{\lambda}'_j)^2 = 1$. In the Majorana basis,

$$\hat{H} = -\frac{it}{2} \sum_j \hat{\lambda}'_j \hat{\lambda}_{j+1} - \frac{i\mu}{2} \sum_j \hat{\lambda}_j \hat{\lambda}'_j. \quad (6)$$

Deep inside the topological superconductor phase, $\mu = 0$, $\hat{H} = -\frac{it}{2} \sum_j \hat{\lambda}'_j \hat{\lambda}_{j+1}$. If we consider the Kitaev chain with L sites and with open boundary conditions, $\hat{H}$ does not include Majorana operators $\hat{\lambda}_1 = \hat{c}_1 + \hat{c}_1^\dagger$ and $\hat{\lambda}'_L = (-i)(\hat{c}_L - \hat{c}_L^\dagger)$. Hence, trivially, we have $[\hat{H}, \hat{\lambda}_1] = [\hat{H}, \hat{\lambda}'_L] = 0$. This means that the modes $\hat{\lambda}_1$ and $\hat{\lambda}'_L$ correspond to zero-energy eigenstates of the single-particle BdG Hamiltonian localized at $j = 1$ and $j = L$, respectively. They exist within the bulk quasiparticle energy gap. Due to these zero-energy modes, there is a twofold degeneracy for the many-body ground states. They are characterized by the fermion number of the fermion operators, $\hat{f} := (\hat{\lambda}_1 + i\hat{\lambda}'_L)/2$ and $\hat{f}^\dagger := (\hat{\lambda}_1 - i\hat{\lambda}'_L)/2$, $\hat{f}^\dagger \hat{f} - 1/2 = -i\hat{\lambda}_1 \hat{\lambda}'_L/2 = \pm 1/2$.

Two-dimensional topological superconductors

As a second example, let us consider a two-dimensional spinless chiral p -wave superconductor (Read and Green, 2000). The BdG Hamiltonian is given by

$$\begin{aligned}\hat{H} &= \frac{1}{2} \int d^2k \left[\hat{c}_{\mathbf{k}}^\dagger, \hat{c}_{-\mathbf{k}} \right] \mathcal{H}(\mathbf{k}) \begin{bmatrix} \hat{c}_{\mathbf{k}} \\ \hat{c}_{-\mathbf{k}}^\dagger \end{bmatrix}, \\ \text{where } \mathcal{H}(\mathbf{k}) &= \begin{bmatrix} \xi_{\mathbf{k}} & \Delta_{\mathbf{k}} \\ \Delta_{\mathbf{k}}^* & -\xi_{\mathbf{k}} \end{bmatrix}, \\ \xi_{\mathbf{k}} &= \frac{k^2}{2m} - \mu, \quad \Delta_{\mathbf{k}} = |\Delta|(k_x - ik_y).\end{aligned}\tag{7}$$

Here, $\mathbf{k} = (k_x, k_y)$ is two-dimensional momentum, and $m, \mu, |\Delta|$, representing the mass of fermions (electrons), chemical potential, and the amplitude of pairing potential, respectively, are real parameters. As we can see from the quasiparticle band structure, there are two phases in this model for $\mu > 0$ and $\mu < 0$ (the so-called weak and strong pairing phases). These two phases are topologically distinct. As before, this can be argued in two different ways. First, we can define a bulk topological invariant. To this end, we define a three-dimensional vector $\mathbf{R}(\mathbf{k})$ as $\mathcal{H}(\mathbf{k}) = \mathbf{R}(\mathbf{k}) \cdot \boldsymbol{\tau}$. We can further normalize $\mathbf{R}$, $\hat{\mathbf{R}}(\mathbf{k}) = \mathbf{R}(\mathbf{k})/|\mathbf{R}(\mathbf{k})|$. Deep inside the strong pairing phase, $\mu \gg 1$, the vector $\hat{\mathbf{R}}(\mathbf{k})$ is localized around the $\hat{\mathbf{R}}_z$ axis. On the other hand, in the weak pairing phase, the trajectory or the surface swept by the vector $\hat{\mathbf{R}}(\mathbf{k})$ is more nontrivial; as $\mathbf{k}$ changes in the two-dimensional momentum space, $\hat{\mathbf{R}}(\mathbf{k})$ wraps the unit sphere once. The topological invariant (the Chern number) is then defined by

$$Ch = \int \frac{d^2k}{4\pi} \hat{\mathbf{R}} \cdot (\partial_x \hat{\mathbf{R}} \times \partial_y \hat{\mathbf{R}}),\tag{8}$$

where $\partial_i = \partial/\partial k_i$. It can be shown that the Chern number is quantized to be integral values as far as there is a gap in the quasiparticle band structure. From the direct calculation, $Ch = 1$ for $\mu > 0$ and $Ch = 0$ for $\mu < 0$. These values reflect the nontrivial/trivial behavior of the $\hat{\mathbf{R}}$ vector mentioned before. For generic quasiparticle band structures with more than two quasiparticle bands, we can use the Thouless-Kohmoto-Nightingale-den Nijs (TKNN) formula to define and calculate the topological invariant,

$$Ch = \frac{1}{2\pi} \int d^2k \sum_a \epsilon_{ij} \partial_i A_j^a(\mathbf{k}),\tag{9}$$

where the sum runs over all quasiparticle bands below zero energy and $A_i^a(\mathbf{k})$ is the Berry connection for the eigenfunction $|u_a(\mathbf{k})\rangle$ of the a -th quasiparticle band, $A_i^a(\mathbf{k}) = i\langle u_a(\mathbf{k}) | \partial_i | u_a(\mathbf{k}) \rangle$. The nontrivial topological character is also reflected in the many-body ground-state wave function. In the weak pairing phase, the ground-state wave function (projected to a sector with a fixed number of particles) is given by the Pfaffian, $\sim \text{Pf}(z_i - z_j)^{-1}$, where $z_i = x_i + iy_i$ is the complexified real-space coordinate of the i -th fermion. The wave function decays algebraically for the distance between fermions. On the other hand, in the strong pairing phase, the many-body ground-state wave function is short-ranged.

Second, in the topologically nontrivial phase, the system supports a chiral edge state. At low energies, the dispersion of the edge state is linear—it is a chiral Majorana (Majorana-Weyl) fermion. At finite temperatures (T), the chiral edge state carries nonzero thermal current, $I = \frac{Ch}{2} \frac{\pi^2 k_B^2}{6h} T^2$. This leads to the thermal Hall conductivity

$$\kappa_{xy} = \frac{Ch}{2} \frac{\pi^2 k_B^2}{3h} T,\tag{10}$$

where we restored the Planck constant h and the Boltzmann constant k_B . This quantization is an analog of the quantized electrical Hall conductivity in the quantum Hall effect. The universal coefficient $Ch/2$ is called chiral central charge. The chiral central charge is an integer for noninteracting fermion systems (e.g., integer quantum Hall states). The fractional value of the central charge is indicative of electron fractionalization and nontrivial topological order. Similarly, a midgap zero-energy state appears in the presence of a superconducting vortex. Similar to the end state of the one-dimensional topological superconductor discussed above, this zero-energy state is a Majorana state.

Three-dimensional topological superconductors

Besides the above examples, there are other kinds of topological superconductors. First, topological superconductors may exist in the presence of symmetries. In the above examples, the only relevant symmetry is the conservation of the fermion number parity. (Here, the fermion number parity conservation simply means Hamiltonians must be bosonic operators. Quite often in the literature, this is not phrased or regarded as symmetry.) We can have other symmetries such as time reversal, spin rotation, and crystallographic symmetries. In some cases, some symmetry is necessary to have a topological distinction between different quantum ground states—they may belong to a symmetry-protected phase. Second, topological superconductors are possible other than one and two dimensions discussed above. For example, topological superconductors protected by TRS can exist in

three spatial dimensions. The B phase of ^3He is an example (the so-called Balian-Werthamer (BW) state). It is described by the BdG Hamiltonian

$$\hat{H} = \frac{1}{2} \int d^3k \begin{bmatrix} \hat{c}_{\mathbf{k}\uparrow}^\dagger & \hat{c}_{\mathbf{k}\downarrow}^\dagger & \hat{c}_{-\mathbf{k}\uparrow} & \hat{c}_{-\mathbf{k}\downarrow} \end{bmatrix} \mathcal{H}(\mathbf{k}) \begin{bmatrix} \hat{c}_{\mathbf{k}\uparrow} \\ \hat{c}_{\mathbf{k}\downarrow} \\ \hat{c}_{-\mathbf{k}\uparrow}^\dagger \\ \hat{c}_{-\mathbf{k}\downarrow}^\dagger \end{bmatrix}, \quad (11)$$

$$\text{where } \mathcal{H}(\mathbf{k}) = \begin{bmatrix} \xi_{\mathbf{k}} & \Delta_{\mathbf{k}} \\ \Delta_{\mathbf{k}}^\dagger & -\xi_{\mathbf{k}} \end{bmatrix},$$

$$\xi_{\mathbf{k}} = \frac{k^2}{2m} - \mu, \quad \Delta_{\mathbf{k}} = |\Delta|(i\sigma_y)\mathbf{k} \cdot \boldsymbol{\sigma},$$

where the Pauli matrices $\sigma_{1,2,3}$ act on spin degrees of freedom. In addition to the particle-hole condition (4), the BdG Hamiltonian also satisfies $\sigma_2 \mathcal{H}(-\mathbf{k})^* \sigma_2 = \mathcal{H}(\mathbf{k})$, that is, TRS. Combined together, we see that the BdG Hamiltonian (11) anticommutes with $\Gamma \equiv \sigma_2 \otimes \tau_1$, $\Gamma \mathcal{H}(\mathbf{k}) \Gamma = -\mathcal{H}(\mathbf{k})$ —we say $\mathcal{H}(k)$ has chiral symmetry (CS). This implies, in the basis where Γ is diagonal, the Hamiltonian takes a block off-diagonal form,

$$\mathcal{H}(\mathbf{k}) = \begin{pmatrix} 0 & D(\mathbf{k}) \\ D^\dagger(\mathbf{k}) & 0 \end{pmatrix}. \quad (12)$$

We note that CS pairs up (nonzero) eigenvalues and eigenvectors of $\mathcal{H}(\mathbf{k})$: It is straightforward to see that when $w_a(\mathbf{k})$ is an eigenvector with eigenvalue $\varepsilon_a(\mathbf{k})$, $\mathcal{H}(\mathbf{k})w_a(\mathbf{k}) = \varepsilon_a(\mathbf{k})w_a(\mathbf{k})$, $\Gamma w_a(\mathbf{k})$ is another eigenvector with eigenvalue $-\varepsilon_a(\mathbf{k})$. CS and the off-diagonal structure are also useful to introduce the topological invariant of the three-dimensional, time-reversal symmetric topological superconductor (superfluid). We first note that $\mathcal{H}(\mathbf{k})^2 = \text{diag}(DD^\dagger, D^\dagger D)$, and hence the eigenvalues of $\mathcal{H}(\mathbf{k})$, $\pm \varepsilon_a(\mathbf{k})$, are obtained by solving

$$DD^\dagger \mathbf{u}_a = \varepsilon_a^2 \mathbf{u}_a, \quad D^\dagger D \mathbf{v}_a = \varepsilon_a^2 \mathbf{v}_a. \quad (13)$$

We then introduce a $\mathbf{k}$ -dependent matrix, $q(\mathbf{k}) := \sum_a \mathbf{u}_a(\mathbf{k}) \mathbf{v}_a^\dagger(\mathbf{k})$ (where $\mathbf{u}_a(\mathbf{k})$ and $\mathbf{v}_a^\dagger(\mathbf{k})$ are column and row vectors, respectively). The topological invariant is then given by (Schnyder et al., 2008)

$$v = \int \frac{d^3k}{24\pi^2} \varepsilon^{ijk} \text{Tr}[(q^{-1} \partial_i q)(q^{-1} \partial_j q)(q^{-1} \partial_k q)] \in \mathbb{Z}, \quad (14)$$

$$i, j, k = x, y, z, \quad \partial_i = \partial_{k_i}.$$

For $\mu > 0$, the topological invariant is $v = 1$ while for $\mu < 0$, it is zero.

Key issues

Periodic table of topological insulators and superconductors

A systematic way to discuss topological superconductors (and topological insulators) in different dimensions and with different symmetries is to utilize the Altland–Zirnbauer symmetry classification (Altland and Zirnbauer, 1997). In this classification, quadratic fermionic Hamiltonians (including the BdG Hamiltonians) are classified in terms of the presence/absence of time-reversal and particle-hole symmetries (spin rotation symmetry also plays a role).

The Altland–Zirnbauer classification concerns BdG Hamiltonians given in the following form:

$$\mathcal{H} = \begin{bmatrix} h & \Delta \\ -\Delta^* & -h^T \end{bmatrix}, \quad (15)$$

$$h^\dagger = h, \quad \Delta = -\Delta^T.$$

Here, h is a normal part (e.g., lattice tight-binding Hamiltonian), and Δ represents superconducting order parameters. For single-particle (BdG) Hamiltonians, we can consider three discrete symmetries, time-reversal, particle-hole, and chiral symmetries. (When the total Hamiltonian $\mathcal{H}$ is invariant under unitary symmetry (e.g., spin-rotation symmetry) and block-diagonalizable, we focus on each irreducible block of $\mathcal{H}$.) TRS is defined by

$$U_T \mathcal{H}^* U_T^\dagger = \mathcal{H}, \quad (16)$$

where U_T is a unitary matrix. For example, using the y component of the spin operator S^y , U_T is given by $U_T = \exp(i\pi S^y)$. Note that, when the time-evolution of a state ψ is given by $i\partial\psi(t)/\partial t = \mathcal{H}\psi(t)$, $\psi' = U_T\psi^*$ obeys the time-reversed Schrödinger equation, $-i\partial\psi'(t)/\partial t = \mathcal{H}\psi'(t)$, if $\mathcal{H}$ satisfies (16). Next, particle-hole symmetry (PHS) is defined by

$$U_C \mathcal{H} U_C^\dagger = -\mathcal{H}, \quad (17)$$

where U_C is a unitary matrix. We note that if we have an eigenstate ψ with eigenvalue ε , $\psi' = U_C \psi^*$ is also an eigenstate with energy $-\varepsilon$.

When $\mathcal{H}$ is invariant under both time-reversal and particle-hole, there is a unitary matrix that anticommutes with $\mathcal{H}$,

$$\mathcal{H} \Gamma = -\Gamma \mathcal{H}, \quad \Gamma = U_T U_C^\dagger. \quad (18)$$

(See the previous example presented around (12).) When such a unitary matrix exists, we say $\mathcal{H}$ is chiral symmetric. It is however possible that a Hamiltonian is chiral symmetric without having time-reversal and particle-hole symmetries.

Furthermore, time-reversal and particle-hole symmetries can be typified into two classes. As well known, time reversal for integer spin particles squares to $+1$ while that for half-odd integer particles squares to -1 . We can make a similar distinction for particle-hole transformations—those that square to $+1$ and -1 . To summarize, by considering the presence/absence of time-reversal and particle-hole symmetries, and when they exist, their types, we have $3 \times 3 = 9$ possible cases. Adding the case where we have neither time-reversal nor PHS, we have 10 different cases in total. These 10 symmetry classes were identified by Altland and Zirnbauer around 1996 in the context of disordered BdG Hamiltonians and random matrix theory.

The 10 symmetry classes are summarized in Table 1. In the leftmost column of the table, A, AI, etc., are nomenclature for the symmetry classes. This is based on the fact that the symmetry classes of Hamiltonians are in one-to-one correspondence with the classification of symmetric spaces by Cartan. The ensemble of generic BdG Hamiltonians satisfying (4) is called symmetry class D. By imposing various symmetries, BdG Hamiltonians can realize five other symmetry classes: DIII, A, AIII, C, and CI. First, imposing TRS leads to symmetry class DIII. If we impose the conservation of S_z , we realize symmetry class A, and, with further requiring TRS, symmetry class AIII. On the other hand, if we impose $SU(2)$ spin rotation symmetry, we realize symmetry class C (without TRS) and CI (with TRS).

For the 10 Altland–Zirnbauer symmetry classes, and a given spatial dimension d , Table 1 summarizes the presence/absence of topological insulators and superconductors, and when they exist, the type of topological invariants (Schnyder et al., 2008; Ryu et al., 2010; Kitaev, 2009). Here, $\emptyset$ means that there are no topological insulators and superconductors, while $\mathbb{Z}$, $\mathbb{Z}_2$, and $2\mathbb{Z}$ mean topological invariants are integer-valued, $\mathbb{Z}_2$ valued, and even integer-valued, respectively. The Kitaev chain and chiral p -wave examples both belong to class D, in $d = 1$ and $d = 2$, respectively. The BW state is a topological superconductor (superfluid) in symmetry class DIII in $d = 3$ dimensions.

Bulk-boundary correspondence and the effect of disorder

In all the three examples we have discussed, the topological superconductors in $d = 1, 2, 3$ spatial dimensions, gapless states (zero-energy Majorana mode for the case of 1d topological superconductor) appear when the system is terminated by a boundary. These states localize near the boundary and are stable against gap-opening by perturbations that respect the symmetries of the system—they are said to be ingappable or ungappable. The presence of these stable boundary states near a boundary is a direct consequence of nontrivial bulk topology.

Furthermore, these boundary states are anomalous in the sense that they cannot be realized on their own in an isolated $(d - 1)$ -dimensional lattice system. In this sense, topological bulk and anomalous boundary systems are inseparable. The close

Table 1 Classification of topological insulators and superconductors.

class	TRS	PHS	CS	$d = 1$	$d = 2$	$d = 3$
A	0	0	0	$\emptyset$	$\mathbb{Z}$	$\emptyset$
AIII	0	0	1	$\mathbb{Z}$	$\emptyset$	$\mathbb{Z}$
AI	+1	0	0	$\emptyset$	$\emptyset$	$\emptyset$
BDI	+1	+1	1	$\mathbb{Z}$	$\emptyset$	$\emptyset$
D	0	+1	0	$\mathbb{Z}_2$	$\mathbb{Z}$	$\emptyset$
DIII	-1	+1	1	$\mathbb{Z}_2$	$\mathbb{Z}_2$	$\mathbb{Z}$
AII	-1	0	0	$\emptyset$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
CII	-1	-1	1	$2\mathbb{Z}$	$\emptyset$	$\mathbb{Z}_2$
C	0	-1	0	$\emptyset$	$2\mathbb{Z}$	$\emptyset$
CI	+1	-1	1	$\emptyset$	$\emptyset$	$2\mathbb{Z}$

The leftmost column (A, AIII, ..., CI) represents 10 symmetry classes of single-particle Hamiltonians classified in terms of the presence or absence of time-reversal symmetry (TRS) and particle-hole symmetry (PHS), as well as chiral symmetry (CS). In the table, the absence of symmetries is denoted by 0. The presence of these symmetries is denoted either by $+1$ or -1 , depending on whether the (antiunitary) operator implementing the symmetry at the level of the single-particle Hamiltonian squares to $+1$ or -1 . d is the spatial dimension. The symbols $\mathbb{Z}_2$, $\mathbb{Z}$ and $2\mathbb{Z}$ indicate the relevant topological invariant is $\mathbb{Z}_2$ -valued, integral-valued, or even integral-valued, respectively [$\emptyset$ means there is no topological invariant (no topologically-nontrivial state)]. The table is partitioned into two groups, classes A and AIII ("complex classes") which do not preserve TRS and PHS, and the rest ("real classes"). If we extend the classification table to arbitrary spatial dimension d , the complex (real) classes exhibit two (eight)-fold periodicity in d .

relation between them is known as bulk-boundary correspondence. Some of the salient features of the bulk-boundary correspondence are as follows. First, as mentioned already, a boundary of a topological bulk system cannot be trivially gapped (while preserving symmetries). For noninteracting systems, this means boundary modes have to be gapless. (In interacting systems and when $(d - 1) = 2$, boundary systems can be topologically ordered instead of being gapless (Vishwanath and Senthil, 2013).) Also, boundary states avoid the so-called fermion doubling theorem (the Nielsen-Ninomiya theorem and its variants), which claims that, in lattice systems, Weyl points should always appear in pairs with zero net chirality. Finally, when the topological properties of a bulk system are protected by some symmetry, the symmetry is not strictly preserved on its boundary. Even though the boundary system may look symmetric classically (i.e., at the level of Hamiltonian or Lagrangian), the symmetry is violated through quantum mechanical effects. This type of symmetry breaking is called quantum anomaly in quantum field theory. All in all, these features of boundary states are not compatible with isolated (fully-regularized) quantum many-body systems, and they have to be realized on a boundary of a higher-dimensional (topological) system.

We have so far assumed that perturbations and deformations in boundary systems are spatially homogeneous. The bulk-boundary correspondence however holds even in the presence of disorder—Gapless boundary states on a boundary of topological systems are stable against disorder. That is, the boundary modes do not Anderson localize even in the presence of disorder, as long as symmetry conditions (if any) are preserved or enforced, and as long as disorder does not alter the bulk topological properties. This is in sharp contrast with regular (lattice) systems, where Anderson localization is ubiquitous and inevitable when disorder is strong enough (as shown originally by Anderson (Anderson, 1958)). The lack of Anderson localization indicates the absence of atomic limit, and, once again, that the boundary system cannot be realized as a $(d - 1)$ -dimensional lattice system. See, for example, Nomura et al. (2007) which demonstrates the lack of Anderson localization on the surface of a $d = 3$ -dimensional topological insulator. In Schnyder et al. (2008) and Ryu et al. (2010), the lack of Anderson localization at boundaries was hypothesized to be the defining property of topological insulators and superconductors and used as a guiding principle to search and classify topological insulators and superconductors.

The effect of interactions

All of the aforementioned examples can be understood in terms of noninteracting or mean-field Hamiltonians. With interactions, some (noninteracting) topological superconductors are stable, while others cease to be topological, that is, once interaction effects are included, they are adiabatically connected to trivial states. Interactions can also give rise to new topological phases that do not exist without interactions. For example, the topological superconductor phase in the Kitaev chain and the weak pairing phase of the chiral p -wave superconductor turn out to be stable even with interactions. On the other hand, the topological classification in symmetry class BDI in $d = 1$ dimension is altered in the presence of interactions. The topological classification at the noninteracting level is $\mathbb{Z}$ (c.f. Table 1). A simple example of topological superconductors in this class is obtained from the Kitaev chain by imposing TRS. This classification, however, in the presence of interactions is known to be modified to $\mathbb{Z}_8$ (Fidkowski and Kitaev, 2010, 2011). Namely, noninteracting topological superconductors with topological invariant being an integer multiple of 8 can be turned into a topologically trivial state by turning on interactions. We say the integral topological classification collapses or is reduced to $\mathbb{Z}_8$.

Beyond the above one-dimensional example, a similar reduction of topological classifications has been established in other symmetry classes in various spatial dimensions. For example, the integer classification of three-dimensional time-reversal symmetric topological superconductors is reduced to $\mathbb{Z}_{16}$. This has been argued, following the spirit of the bulk-boundary correspondence, by studying surface states of 3d topological superconductors (Fidkowski et al., 2013; Wang and Senthil, 2014; Metlitski et al., 2014; You and Xu, 2014; Kitaev, 2015; Morimoto et al., 2015). Furthermore, topological quantum field theory approaches have been developed (along with the developments of symmetry-protected topological phases in general) (Kapustin et al., 2015; Witten, 2016; Freed and Hopkins, 2021).

Conclusion

Topological superconductors have become an active field of research, with exciting new discoveries being made constantly. In this article, we mainly focused on fully gapped ones within the BdG (mean-field) formalism. The theory of topological superconductors and related topological systems has been vastly expanding, and there are many topics that we cannot discuss in this article.

One notable omission is the topic of gapless topological superconductors. Nodal systems, such as semimetals and nodal superconductors, can exhibit nontrivial band topology, even though the bulk gap closes at certain points in the Brillouin zone. The Fermi surfaces (superconducting nodes) of these gapless materials are topologically protected by topological invariants, which are defined in terms of an integral along a surface enclosing the gapless points. Similar to fully gapped topological systems, the topological characteristics of nodal materials manifest themselves at the surface in terms of gapless boundary modes. Depending on the symmetry properties and the dimensionality of the bulk Fermi surface, these gapless boundary modes form Dirac cones, Fermi arcs, or flat bands. Topological nodal systems can be protected by nonspatial symmetries (i.e., time-reversal or PHS) as well as spatial lattice symmetries, or a combination thereof. Examples of gapless topological superconductors include two-dimensional $d_{x^2 - y^2}$ -wave superconductors (Hu, 1994) and the A phase of superfluid ^3He (Volovik, 2011, 2003).

Other topics that we did not have space to discuss include, for instance, topological classification in the presence of crystalline symmetries (topological crystalline superconductors), higher-order topology (Benalcazar et al., 2017), and topological superconductors that can emerge in dynamical settings such as topological Floquet superconductors (Jiang et al., 2011).

In terms of material realization, a variety of systems have been discussed in search of topological superconductors and Majorana fermions. Despite the abundance of examples of topological insulators, topological superconductors remain rare, and to conclude decisively the realization of topological superconductors has been more subtle and difficult. This is partly because an unconventional pairing symmetry is required for a topologically nontrivial state. However, zero-energy Majorana bound states have also been explored in heterostructures involving *s*-wave superconductors. Examples of this type of setup are a superconductor-magnet domain wall along the edge of a two-dimensional quantum spin Hall insulator (Fu and Kane, 2009), or a Chern insulator interface (Qi et al., 2010; Cheng, 2012; Lindner et al., 2012; Vaezi, 2013; Clarke et al., 2013; Barkeshli et al., 2013; Mong et al., 2014). Another example is a flux vortex across a superconducting interface between three-dimensional topological and trivial insulators (Fu and Kane, 2008). In these examples, *s*-wave superconductors are not topological. Nevertheless, these systems still support zero-energy Majorana bound states, and nontrivial topological invariants can be defined for the heterostructures (defects) themselves (Teo and Kane, 2010). In an even broader context, beyond the regular superconductors, the physics of topological superconductors and Majorana fermions are relevant to $\nu = 5/2$ fractional quantum Hall states (paired states of composite fermions) (Moore and Read, 1991; Greiter et al., 1992), and the Kitaev spin liquid (Kitaev, 2006).

Abstract

Superinsulation is a state of matter in which the electrical conductivity vanishes in the finite-temperature range between zero and the superinsulating transition temperature. This state is dual to superconductivity, where the resistance vanishes within a similar finite-temperature interval. The phenomenon of superinsulation arises in certain quantum materials possessing either inherent or self-induced granularity. In these materials the effective electromagnetic action contains magnetic monopoles. When these proliferate, the Coulomb interactions dominate magnetic interactions. In two dimensions (2D), magnetic monopole instantons turn the Coulomb interaction between two charges of the opposite signs into a linear attractive potential causing the same charge confinement that holds quarks together in hadrons and, therefore, leading to an infinite electric resistance even at finite temperatures. In three dimensions (3D), a superinsulator harbors a condensate of magnetic monopoles resulting in a similar charge confinement. The phenomenon of superinsulation has been experimentally discovered and studied in nearly 2D thin superconducting films of materials with a large normal-state dielectric permittivity and in generic granular superconductors.

Key points

The article gives an introductory description of the superinsulation, specifically focusing on:

- The role of magnetic monopoles in materials
- Showing that planar superconductors are governed by a topological gauge field theory
- Deriving the quantum and thermal phase structure of planar superconductors
- Illustrating the magnetic–electric duality between the superconducting and superinsulating phases, with zero and infinite electric resistance, respectively
- Discussing the nature of superinsulators and showing that they realize an Abelian version of the confinement that holds quarks together in hadrons
- Proposing that an oblique version of superinsulation may be realized in the pseudogap state of high temperature superconductors
- Discussing the role of disorder

Introduction

Superinsulation, a state of matter mirror dual to superconductivity, refers to the complete disappearance of the electrical conductivity in certain materials when they are cooled below a certain critical transition temperature. Superconductivity is a phenomenon whereby an electric current flows through a material, called superconductor, even in the absence of applied voltage hence without resistance. Accordingly, a superinsulator is a material that does not conduct electricity despite applied voltage, hence having infinite resistance.

Superinsulation emerges because of the electric–magnetic symmetry of laws of nature. To place electric and magnetic fields on equal footing, one has to introduce magnetic charges q_g as a dual mirror of electric charges q_e . Then electric–magnetic symmetry manifests as a symmetry under simultaneous interchange of electric and magnetic fields, $\mathbf{E} \rightarrow \mathbf{B}$, $\mathbf{B} \rightarrow -\mathbf{E}$, and electric and magnetic charges, $q_e \leftrightarrow q_g$. Magnetic charges are perfectly consistent in a quantum theory of electromagnetism, provided the product of electric and magnetic charges is quantized, as shown in a seminal work by Dirac in the 1930s (Dirac, 1931). Magnetic charges, called magnetic monopoles, appear naturally in the most grand-unified theories (GUTs) of particle interactions (Goddard and Olive, 1978) and are a cornerstone of the superinsulation phenomenon. Despite good 40 years of intensive search, however, they have never been detected in any high-energy experiment.

While the GUT monopoles are elusive, other Abelian $U(1)$ monopoles can lead to notable effects. As Polyakov pointed out (Polyakov, 1975), there are two possible kinds of electromagnetism, the noncompact one, with gage group $\mathbb{R}$ and the compact one, with the gage group $U(1)$. In classical physics, where only equations of motion matter, there is no real distinction between the two. At the quantum level, however, things become different: it is the compact quantum electrodynamics (QED) that admits magnetic monopoles, see Polyakov (1987). There are two ways of obtaining compact QED: either one considers it as a surviving low-energy theory after spontaneous symmetry breaking of a larger compact group, or one formulates it on a lattice. Either way, compact QED is an effective theory, with an ultraviolet (UV) cutoff.

Already in the 1970s it was realized that dual superconductivity and related Abelian magnetic monopoles in the $U(1)^{N-1}$ subgroup of $SU(N)$ offer a model for quark confinement via the dual Meissner effect that squeezes color-electric fields into thin tubes, strings, linearly binding quarks into hadrons (Mandelstam, 1976; Nambu, 1974; 't Hooft, 1978). This mechanism can also take place in other settings. Integrating out the matter degrees of freedom, the nonrelativistic Maxwell action becomes the effective action for insulators. If this effective action is compact, it admits magnetic monopoles, which can lead to confinement, see Greensite (2011) of electric charges by squeezing electric flux into thin tubes as shown in Fig. 1. This is a new, superinsulating phase of insulators.

The idea that the electric–magnetic duality, resulting in charge confinement, is realized in condensed matter physics was first proposed in 1996 in the context of Josephson junction arrays (JJAs) (Diamantini et al., 1996) and the ensuing new state of matter was called *superinsulator* since it is characterized by an infinite electrical resistance (Diamantini et al., 1996). The duality in terms of charges and vortices was subsequently surmised in numerical simulations (Krämer and Doniach, 1998). In 2008, superinsulation was independently proposed as a new state of matter emerging in thin superconducting films (Vinokur et al., 2008; Baturina and Vinokur, 2013) as a manifestation of the uncertainty principle relating amplitude and phase of the superconducting order parameter. Experimentally, superinsulation has been detected in TiN (Baturina et al., 2007; Vinokur et al., 2008) and NbTiN (Mironov et al., 2018) films and in InO (Sambandamurthy et al., 2005) and NbSi (Humbert et al., 2021) films.

The superinsulating state, detected again later in InO (Ovadia et al., 2015), was referred there as “finite-temperature insulator” and was associated with charge carriers overheating (Basko et al., 2007; Altshuler et al., 2009). Here, however we would like to dispel the view that overheating is a “description of the nature” of this new state of matter. It is most certainly not. Overheating is a possible model of how this state is destroyed in a dynamical phase transition when a sufficiently strong applied voltage is applied. A model of the new state must explain why the charges become immobile below a transition temperature in the first place. The idea behind overheating is that this is due to many-body localization (MBL) (Altshuler et al., 2006), a model that has been studied in 1D but for which there is no established support in 2D, let alone for the essentially 3D InO films, in which the coherence length is quite smaller than the thickness. In the section below dedicated to the role of disorder, we show how recent experimental data essentially rule out this idea.

Superinsulation appears as an inherent feature of the superconductor–insulator transition (SIT) at low temperatures. In superconducting films with a large normal-state dielectric permittivity, the Coulomb interaction becomes logarithmic over the entire system and competes with the magnetic interaction between vortices (Baturina and Vinokur, 2013). When two interactions are

Fig. 1 Confinement of Cooper pairs by a magnetic monopole condensate. Left panel illustrates the usual 3D Coulomb interaction between two charges q_1 and q_2 of opposite signs. Right panel illustrates that, in full analogy with the charge condensate currents squeezing magnetic field into thin filaments, Abrikosov vortices, the magnetic condensate currents squeeze electric field lines into electric strings with the linear tension σ . As a result, the attracting interaction between charges grows linearly with the separation distance r . Reproduced from Baturina TI and Vinokur VM (2013) Superinsulator–superconductor duality in two dimensions. *Annalen der Physik* 331: 236–257.

Fig. 2 Sheet resistance as a function of temperature for a TiN film (Diamantini et al., 2019). The *dashed straight line* in this logarithmic scale is the activated Arrhenius behavior typical of insulators. The deviation at very low temperatures shows the hyperactivated behavior indicating superinsulation. The deviation becomes stronger when a magnetic field is applied. Reproduced from Diamantini MC et al. (2019) The superconductor-superinsulator transition: S-duality and the QCD on the desktop. Journal of Superconductivity and Novel Magnetism 32: 47–51.

comparable, the superconducting condensate breaks down into separate superconducting granules connected via Josephson links. This granular array hosts superconducting islands (Sacépé et al., 2008, 2011; Kowal and Ovadyahu, 1994; Fistul et al., 2008) intertwined with the coreless Josephson vortices (Diamantini et al., 2020a, 2021b). Superinsulation arises due to instability of these vortices upon further increase of the 2D Coulomb interaction. Magnetic monopole instantons (Polyakov, 1987), corresponding to vortex tunneling events, cause the Coulomb interaction between charges to become linear (Diamantini et al., 2018), see Fig. 1 so that only neutral “electric pions” survive at large distances and charge transport is suppressed (Diamantini et al., 2020b). The result is the *hyperactivated* behavior of the sheet resistance as function of temperature, the exemplary $R_{\square}(1/T)$ dependence being shown in Fig. 2.

In the following exposition, we use natural units $c = 1$, $\hbar = 1$, $\epsilon_0 = 1$.

Gauge theories of planar superconductors

The vicinity of the SIT is governed by the interplay of two topological phenomena, mutual statistics Aharonov–Bohm–Casher (ABC) interactions (Aharonov and Bohm, 1959; Aharonov and Casher, 1984) between Cooper pairs and Josephson vortices and their Berezinskii–Kosterlitz–Thouless (BKT) (Berezinskii, 1971; Kosterlitz and Thouless, 1972, 1973) topological phase transitions. In the critical vicinity of the SIT the films acquire a self-induced electronic granular structure, and they have to be viewed as arrays of superconducting condensate droplets with the characteristic size $\ell \simeq \mathcal{O}(\xi)$, where ξ is the superconducting coherence length, coupled via Josephson links, that is, as a JJA. The vortices in the system are Josephson vortices which, unlike Abrikosov vortices, do not have a normal core. Above the vortex–BKT transition, that is, above the vortex unbinding temperature T_{VBKT} , the Josephson vortices have topological mutual statistics interactions with the out-of-condensate Cooper pairs that emerge there. Moreover, as Josephson vortices do not have normal cores, their dynamics acquires ballistic character (van Otterlo et al., 1994; van der Zant et al., 1992). As a consequence, the description of the SIT and planar superconductivity is achieved by the topological gauge theory presented below.

En passant we remark that the XY model, adapted to describe 2D superfluids and viewed as an equivalent to the Coulomb gas picture (Minnhagen, 1987), is often applied also to charged superconductors. However, although it captures several experimental features fairly well, it does not account for the mutual statistics topological interactions and ballistic dynamics of Josephson vortices, hence misses topological aspects of 2D superconductivity that are essential near the SIT.

The ABC topological interactions are encoded in the phase acquired by the wave function of one of the types of the excitation, say a charge, when it encircles the other, say a vortex, Aharonov–Bohm effect (Aharonov and Bohm, 1959), and vice versa, Aharonov–Casher effect (Aharonov and Casher, 1984). These interactions (Wilczek, 1990) are infrared (IR)-dominant since they have an infinite interaction range. In the Euclidean partition function describing point charges and vortices they must be accounted for by the topological Gauss linking number of their trajectories. This topological invariant is nonlocal, but, as noted by Wilczek (1992), can be turned local by coupling the point charge and vortex currents, Q_{μ} and M_{μ} to

two fictitious gage fields a_μ and b_μ with mixed Chern–Simons term (Jackiw and Templeton, 1981; Deser et al., 1982a, b), resulting in the Euclidean partition function

$$Z = \sum_{\{Q_\mu, M_\mu\}} \int \mathcal{D}a_\mu \mathcal{D}b_\mu e^{-S}, \quad (1)$$

$$S = \int d^3x \frac{i}{2\pi} a_\mu \epsilon^{\mu\alpha\beta} \partial_\alpha b_\beta + i a_\mu Q_\mu + i b_\mu M_\mu.$$

This same model can also be derived from another point of view. Following Wen and Zee (1992) in their derivation of the long-distance effective field theories of incompressible quantum Hall states, one can define topologically conserved charge and vortex currents in terms of the curl of a fictitious pseudovector field b_μ and a fictitious vector field a_μ :

$$j^\mu = \frac{1}{2\pi} f^\mu = \frac{1}{2\pi} \epsilon^{\mu\alpha\beta} \partial_\alpha b_\beta, \quad (2)$$

$$\phi^\mu = \frac{1}{2\pi} g^\mu = \frac{1}{2\pi} \epsilon^{\mu\alpha\beta} \partial_\alpha a_\beta.$$

The fields a_μ and b_μ are gauge fields, since physical currents are left invariant under the gauge transformations $a_\mu \rightarrow a_\mu + \partial_\mu Y$ and $b_\mu \rightarrow b_\mu + \partial_\mu \Psi$, where Y and Ψ are arbitrary scalar functions. The effective action involving charges and vortices must therefore be a gauge theory. The IR-dominant gauge invariant term which preserves the parity ($\mathcal{P}$) and time-reversal ($\mathcal{T}$) symmetries is the mixed Chern–Simons term. If the gauge group is $U(1)$, the gauge fields are compact. In a lattice formulation, as appropriate for a granular system of the typical size ℓ , the gauge functions are angular variables defined in the domain $[-\pi, +\pi]$. To enforce this periodicity we must introduce integer-valued link variables Q_μ and M_μ , and we are back to Eq. (1).

The Chern–Simons term describes only the topological interactions. To include the dynamics of both charges and vortices, one adds all the possible local gauge invariant terms. This results in the most general (Euclidean) effective action which encodes all the physics of a 2D system of interacting charges and vortices (Diamantini et al., 1996, 2020a)

$$S = \sum_x i \frac{\ell_0^2}{2\pi} a_\mu k_{\mu\nu} b_\nu + \frac{\ell_0^2}{2e_v^2 \mu} f_0^2 + \frac{\ell_0^2 \epsilon}{2e_v^2} \mathbf{f}^2 + \frac{\ell_0^2}{2e_q^2 \mu} g_0^2 + \frac{\ell_0^2 \epsilon}{2e_q^2} \mathbf{g}^2 + \sum_{x,i} i \ell_0 a_0 Q_0 + i \ell_0 a_i Q_i + i \ell_0 b_0 M_0 + i \ell_0 b_i M_i, \quad (3)$$

where $\ell_0 = \ell/\nu$ is the lattice spacing in the Euclidean time direction, ν is the speed of light in the material, and $k_{\mu\nu}$ is the lattice version of the Chern–Simons term (Diamantini et al., 1996), whose exact form is not of importance for what follows.

There are four phenomenological parameters in this action. The couplings e_v^2 and e_q^2 distinguish between the electric and magnetic sectors of the theory and have canonical dimension [1/length]. The dimensionless parameters ϵ and μ distinguish between “electric” and “magnetic” components within the sector and represent the relative dielectric permittivity and magnetic permeability. Correspondingly, $v = 1/\sqrt{\mu\epsilon}$ is the light velocity in the material. In materials that manifest superinsulating behavior $v \ll 1$ so that the “magnetic” components are suppressed with respect to “electric” ones. The two extreme cases, $\mu = 1$, $\epsilon \gg 1$ and $\epsilon = 1$, $\mu \gg 1$ correspond to superconducting thin films and to fabricated JJAs respectively (Fazio and van der Zant, 2001). In this latter case the effective field theory (3) becomes exact in the limit $\mu \rightarrow \infty$ when the ballistic term for vortices is included with a particular mass that makes the model self-dual.

Superconducting films

Superconducting films are characterized by two spatial scales, the thickness, d , and the London penetration depth, λ_L , of the material. The couplings of the effective gage theory are expressed in terms of these two scales,

$$e_q^2 = \mathcal{O}\left(\frac{e^2}{2\pi d}\right), \quad (4)$$

$$e_v^2 = \mathcal{O}\left(\frac{\pi}{e^2 \lambda_\perp}\right) = \mathcal{O}\left(\frac{\pi d}{e^2 \lambda_L^2}\right),$$

where $\lambda_\perp = \lambda_L^2/d$ is the so-called Pearl length (Tinkham, 1996) and represents the electric and magnetic energies of a fundamental granule. The topological interaction induces a spectrum gap (Jackiw and Templeton, 1981; Deser et al., 1982a, b). Both charge and vortex fluctuations acquire the dispersion relation

$$E = \sqrt{m^2 v^4 + v^2 p^2}, \quad (5)$$

with the topological mass

$$m = \frac{e_q e_v}{2\pi v} = \mathcal{O}\left(\frac{1}{v \lambda_L}\right), \quad (6)$$

The parameters e_q^2 and e_v^2 can be traded for this topological mass $m = e_q e_v / 2\pi v$ and one dimensionless parameter $g = e_v / e_q = \mathcal{O}(d/(\alpha \lambda_L))$, where $\alpha = e^2/4\pi$ is the fine structure constant. The parameter g plays the role of a dimensionless conductivity.

Josephson junction arrays

The Hamiltonian for an exemplary square JJA comprising superconducting islands with spacing ℓ and characterized by phases φ , voltages V and nearest-neighbor Josephson coupling of strength E_J is given by (Fazio and Schön, 1991)

$$H = \sum_{\mathbf{x}} \frac{C_0}{2} V_{\mathbf{x}}^2 + \sum_{\langle \mathbf{x}\mathbf{y} \rangle} \frac{C}{2} (V_{\mathbf{y}} - V_{\mathbf{x}})^2 + E_J \left(1 - \cos(\varphi_{\mathbf{y}} - \varphi_{\mathbf{x}}) \right). \quad (7)$$

Here each island has a self-capacitance C_0 and C are mutual capacitances to its nearest neighbors. This Hamiltonian can be also expressed in terms of the integer number $q_{\mathbf{x}}$ of Cooper pairs on the islands

$$H = \sum_{\mathbf{x}} 4E_C q_{\mathbf{x}} \frac{1}{C_0/C - \nabla^2} q_{\mathbf{x}} + \sum_{\mathbf{x}, i} E_J (1 - \cos(\Delta_i \varphi_{\mathbf{x}})), \quad (8)$$

where $E_C = e^2/2C$ is the scale of the charging energy and Δ_i denotes the finite difference operator in direction i . In the self-capacitance limit $C_0 \rightarrow 0$, and adding the vortex kinetic term with the topological mass of Eq. (6) (Diamantini et al., 1996), one finds that the zero-temperature partition function corresponding to this Hamiltonian has precisely the action of the effective gage theory (3) in the limit $\varepsilon = 1$, $\mu \rightarrow \infty$, with the substitutions

$$\begin{aligned} v e_v^2 &\rightarrow 4\pi^2 E_J, \\ v e_q^2 &\rightarrow 8E_C, \end{aligned} \quad (9)$$

so that

$$\begin{aligned} g &\rightarrow \sqrt{\frac{\pi^2 E_J}{2E_C}}, \\ \Delta_{\text{top}} = mv^2 &= \frac{v e_v e_q}{2\pi} \rightarrow \sqrt{8E_C E_J} = \omega_P, \end{aligned} \quad (10)$$

where ω_P is the plasma frequency of the array. Again, the dimensionless coupling governing the phase structure of the array is the ratio of the two magnetic and electric energy scales in the problem. Here, it becomes explicit that this parameter indeed governs the conductivity of the array. The role of the topological energy gap, Δ_{top} , is taken by the plasma frequency, describing small phase oscillations at the superconducting islands of the array.

The quantum phases in the vicinity of the SIT

Quantum phase diagram at $T = 0$

Given that e_q^2 and e_v^2 have the canonical dimension $[1/\text{length}]$ and, correspondingly, the two kinetic terms in (3) are IR-irrelevant, one might be tempted to leave them out and consider only the IR-dominant mixed Chern–Simons theory. Unfortunately, this leads to wrong results and the origin of the problem lies exactly in the role of the quantized charges and vortices associated with the compactness of the two gage groups. The important point is that the “topological limit” $e_q^2 \rightarrow \infty$ and $e_v^2 \rightarrow \infty$ is not well defined without specifying the value of g in this limit. The behavior of quantized charges and vortices depends crucially on this value and, as a consequence one obtains very different ground states when g is varied, typically by changing the film thickness, applying a magnetic field or gate voltages, as shown in Fig. 3.

In the framework of the gauge theory, the SIT is a material realization of the field-theoretic S-duality which expresses the above mentioned invariance of Maxwell’s equation under the exchange of electric and magnetic fields and charges. The structure of the phase diagram is governed by the dimensionless conductivity g and the additional dimensionless parameter η describing the strength of quantum fluctuations. Near the SIT, where $e_q \approx e_v$, η acquires the form (in physical cgs units)

$$\eta = \frac{1}{\alpha} \frac{\pi \ell}{\mu_e \lambda_{\perp}} G \left(\frac{\ell}{2\alpha \lambda_{\perp}} \right), \quad (11)$$

where $\alpha = e^2/\hbar c \approx 1/137$ is the fine structure constant, $\mu_e = \mathcal{O}(1)$ is the positional entropy contribution to the free energy of the system, and G is the diagonal element of the 3D Green function describing electromagnetic interactions screened by the CS mass:

$$G(m\ell v) = \frac{1}{(2\pi)^3} \int_{-\pi}^{\pi} d^3 k \frac{1}{(m\ell v)^2 + \sum_{i=0}^2 4 \sin\left(\frac{k_i}{2}\right)^2}. \quad (12)$$

Identifying the UV cutoff with the superconducting coherence length ξ yields the geometric factor as $d/(\kappa \lambda_L)$, where $\kappa = \lambda_L/\xi$ is the Landau–Ginzburg parameter.

The parameter η plays the role analogous to the role of the inverse of the Ginzburg–Landau parameter of 3D superconductors. For $\eta < 1$, there is a direct transition from a superconductor to a superinsulator, whose exact nature is the subject of the next section. This direct phase transition is the first-order quantum transition in the sense that it goes via a region of coexistence of both states

Fig. 3 The possible quantum phases ($T = 0$) of an interacting system of charges and vortices as a function of the dimensionless conductance g which controls the relative strength of the vortex interaction with respect to the Coulomb interaction. The parameter η is a function of the ratio ℓ/λ_L of the granule size to the penetration depth of the bulk superconductor and controls the presence/absence of an intermediate state in the transition.

around the value $g = 1$. At this self-dual point $g = 1$, the system is a universal metal with exactly the quantum of sheet resistance, $R_\square = R_Q = h/4e^2$ (Fisher and Grinstein, 1988; Fisher, 1990a; Fisher et al., 1990b; Girvin et al., 1992). For $\eta > 1$, which is realized when the granule size and the London penetration depths are comparable, quantum fluctuations destroy both Cooper pairs and monopole condensates and the universal metal point opens up to a full fledged metal phase made of bosons (Diamantini et al., 1996), the so-called Bose metal (Das and Doniach, 1999, 2001; Dalidovich and Phillips, 2002; Phillips and Dalidovich, 2003), see for a review (Kapitulnik et al., 2019). This Bose metal is nothing else but the bosonic topological insulator (Lu and Vishwanath, 2012; Yang and Senthil, 2013; Chen et al., 2013), with a bulk frozen by the topological gap caused by the mutual statistics interactions and symmetry-protected edge states giving rise to the metallic behavior (Diamantini et al., 2020a). The two quantum transitions between superconductor and bosonic topological insulator and between bosonic topological insulator and superinsulator are quantum BKT transitions (Diamantini et al., 2020a). The point where all three transitions meet is a quantum tri-critical point. In the vicinity of this tri-critical point, the geometric scales of the problem satisfy the relation $\ell = d/\alpha$. This indicates that the transition from superconducting to superinsulating behavior is caused by strong quantum fluctuations.

Finite temperature phase diagram

Fig. 4 shows the finite-temperature phase diagram for $\eta > 1$. Both the phase transitions are BKT transitions, one corresponding to vortex unbinding (for the superconductor) and one to charge unbinding (for the superinsulator) (Mironov et al., 2018). The two critical conductances satisfy the self-dual relation $g_1 g_2 = 1$ around the quantum resistance value $g = 1$.

In the phase diagram presented in Fig. 4 we have sketched the behavior of the topological gap $\Delta(g)$ in the bosonic topological insulator phase (*red dashed line*) and we have marked by horizontal dashed lines what experiments, necessarily done at various finite temperatures, would see. For temperatures sufficiently above the topological gap, charges are essentially free in the intermediate state and we have the usual superconductor-to-metal transition. When the temperature is below the topological gap, an experiment would detect simply the transition from a superconductor to an activated insulator. This is the origin of the by now paradigmatic name “superconductor-to-insulator” transition (SIT) (Fazio and Schön, 1991; Fisher and Grinstein, 1988; Fisher, 1990a; Efetov, 1980; Haviland et al., 1989; Hebard and Paalanen, 1990). At extremely low temperatures the bulk becomes effectively frozen and the Bose metal (Kapitulnik et al., 2019) conduction by edge modes starts to be detected. This behavior is seen also in fabricated devices (Böttcher et al., 2018). However, only at temperatures and conductivities g low enough can the transition to a superinsulator be detected. At $T = 0$ the full quantum regime is realized and an experiment would record a transition from a superconductor to a superinsulator with a Bose metal intermediate phase (Diamantini et al., 2020a).

The nature of the superinsulator

Describing quark interactions within hadrons, ‘t Hooft (1978) put forth an appealing confinement mechanism and coined the term “superinsulator” for the confined quark matter with infinite chromo-electric resistance (‘t Hooft, 1978). Polyakov showed (Polyakov, 1987) that this confinement mechanism occurs also in Abelian gauge theories, provided they are compact and hence support topological excitations and magnetic monopoles, which are instantons in 2D and solitons in 3D.

Fig. 4 The finite-temperature phase diagram of an interacting charge–vortex system for the case $\eta > 1$. The transitions are vortex and charge BKT transitions with critical temperatures T_{VBKT} and T_{CBKT} , respectively. The red dashed line marks the behavior of the topological gap $\Delta(g)$ in the bosonic topological insulator phase while the horizontal black dashed lines sketch the transitions seen by an experiment done at the respective temperatures. Reproduced from Trugenberger CA et al. (2020) Magnetic monopoles and superinsulation in Josephson junction arrays. *Quantum Reports* 2: 388–399.

Remarkably, this Abelian confinement emerges in a condensed matter realization of superinsulators. These electric superinsulators constitute a state of matter with infinite resistance at finite temperatures due to electric strings binding Cooper pairs into “electric mesons.” Coupling the matter charge current j^μ to the real electromagnetic gauge potential A_μ , $S \rightarrow S + i \sum_x \ell_0 \ell^2 A_\mu j_\mu$ in the Euclidean action (with ℓ_0 being the minimal length along the time axis), and integrating out all matter variables, one obtains the effective action describing the electromagnetic response of a system. For the bosonic topological insulator, this is

$$S_{\text{eff}}(A_\mu) = \frac{1}{2e_{\text{eff}}^2} \sum_x \mathbf{E}_x^2, \quad (13)$$

with the effective coupling constant

$$e_{\text{eff}}^2 = \mathcal{O}\left(\frac{1}{g}\right) = \mathcal{O}\left(\frac{e^2 \lambda_L}{d}\right), \quad (14)$$

This is the electromagnetic response of a Mott insulator with high dielectric permittivity so that the electric field $\mathbf{E}$ dominates the action. The effective coupling e_{eff}^2 characterizes the strength of the Coulomb interaction, which grows with decreasing g , in particular, with decreasing film thickness d .

In the superinsulating phase the effective action becomes

$$S_{\text{eff}}(A_\mu) = \frac{1}{2e_{\text{eff}}^2} \sum_x \mathbf{E}_x^2 + \frac{2\pi^2}{e_{\text{eff}}^2} \sum_x m_x \frac{1}{-\nabla^2} m_x, \quad (15)$$

where m_x are dynamic magnetic monopole instantons, as shown in Fig. 5, over which one has also to sum in the partition function.

Contrary to charges, whose conservation is ensured by the Noether theorem, Josephson vortices are topological excitations, characterized by the topological quantum number labeled by the homotopy group $\Pi_1(\text{U}(1)) = \mathbb{Z}$, which in this case is the winding number of the longitudinal component of the gauge field. Such topological quantum numbers can vary in local tunneling events, called instantons, which appear as particles in the Euclidean space-time lattice (Coleman, 1985). These Euclidean particles are (nonrelativistic) magnetic monopoles (Polyakov, 1975). In the relativistic limit, magnetic monopoles interact via the 3D Euclidean Coulomb potential and are, thus, always in a plasma phase (Polyakov, 1975). In the present case, since only electric fields enter the game, the interaction is the logarithmic 2D Coulomb potential (Trugenberger et al., 2020), to which the standard treatment of the 2D Coulomb gas (Minnhagen, 1987) with the temperature replaced by the effective coupling e_{eff}^2 applies. In particular, at small e_{eff}^2 , that is, large g , the monopoles are confined and the electromagnetic response of the system coincides with the electromagnetic response of the bosonic topological insulator. However, monopoles unbind if e_{eff}^2 is sufficiently large, that is, if g is sufficiently small, and the Coulomb interaction becomes stronger than its critical value. The resulting monopoles’ “endogenous disorder” squeezes electric fields created by neighboring electric charges of opposite signs into thin electric flux tubes, Polyakov’s electric strings, dual to superconducting Abrikosov vortices, see, for example, Tinkham (1996). This induces a linear electric potential $V_{\text{string}} = \sigma L$ between the two probe charges at distance L . Hence, the charges can be viewed as bound by a string with the tension (Diamantini et al., 2020b)

$$\sigma = \frac{\sqrt{8e_{\text{eff}}}}{\pi \ell_0 \ell} e^{-\frac{\pi^2}{e_{\text{eff}}} G_2(0)}, \quad (16)$$

where $G_2(0)$ is the IR-regularized 2D lattice Coulomb potential at the coinciding points.

When the two probe charges are separated by distances larger than the typical string length $d_s = 1/\sqrt{\sigma}$ on which the tension starts to be felt, a couple Cooper pair–Cooper hole emerges out of the vacuum to form two short strings replacing the long one. This is the

Fig. 5 A (nonrelativistic) magnetic monopole instanton. The flux 2π on a plaquette formed by 4 granules disappears in a tunneling event between times t and $t + \ell_0$. . Reproduced from Diamantini MC et al. (2020b) Direct probe of the interior of an electric pion in a Cooper pair superinsulator. Communications on Physics 3: 142

property of *confinement*, the mechanism holding quarks together in color-neutral hadrons (Greensite, 2011). This, of course, assumes dynamical matter but indeed, confinement by U(1) monopoles survives when dynamical matter is coupled to the gage fields, at least for one species of relativistic fermions (Nogueira and Kleinert, 2008). Confinement means that, on large scales, the spectrum of the theory does not contain charged Cooper pairs anymore but only neutral electric “pions.” As a consequence, the system, if large enough, acquires infinite resistance, which holds up to the temperature of the charge BKT transition, T_{CBKT} .

Asymptotic freedom and size effects

Confining strings are characterized by two scales, the typical length after which tension is felt, d_s , and the width, w . The latter is set by the photon mass, the gap characterizing the superinsulating phase, $w = 1/m_{\text{ph}}$ (Polyakov, 1975, 1987). Contrary to strings in quantum chromodynamics, the width and length of these Abelian strings scale differently with the coupling constant (Caselle et al., 2016) so that in the physical regime, the Abelian strings are thin and long.

The confinement scale $d_s = 1/\sqrt{\sigma}$ sets the dimension of the neutral bound states. In quantum chromodynamics, the strong interaction binding quarks implies that mesons and hadrons are extremely small and it is impossible to “look inside” them. Quarks can be observed only indirectly, by smashing hadrons in colliders and observing the jets formed in these collisions. The electric forces in superinsulators are much weaker than the strong interactions; hence electric pions are much larger than their elementary particle cousins and it is conceivable that one can measure their interior simply by experimenting on small enough samples.

What would one expect in this interior? Non-Abelian gage theories are characterized by the phenomenon of asymptotic freedom (Gross, 1999), the coupling constant, and thus the strength of the interaction, flows to zero at short scales. While this is the original point of view from the vicinity of the Gaussian UV fixed point, asymptotic freedom can be understood also from the point of view of the IR string theory, where gauge interactions become nonperturbative. This is the statement that the string tension decreases, and eventually vanishes, when approaching short scales, where perturbative gauge interactions take over. This is particularly important in the present case, where we have two clearly distinct scales. At intermediate observation scales $w = 1/m_{\text{ph}} < r_{\text{obs}} < d_s$, Cooper pairs feel neither the string tension nor the standard Coulomb potential, which is screened by the photon mass on scales larger than w . One can thus expect that the hyperactivated resistance behavior caused by the string should give way directly to a saturated metallic resistance when the sample size decreases below the critical threshold d_s . This is fully confirmed in experiment (Diamantini et al., 2020b), as shown in Fig. 6.

Electric Meissner effect and its manifestation in the $I(V)$ characteristics

Exactly as superconductivity can be destroyed by the application of a strong enough magnetic field, superinsulation does not survive the application of a sufficiently strong electric field, that is, an external voltage. An electric field E decreases the effective linear potential of Cooper pairs separated by the distance L to $U_{\text{eff}} = (\sigma - 2eE)L$. Below the critical value $V_{\text{c1}} = \sigma(T)L/2e$, however, the effective string tension $\sigma_{\text{eff}}(T)$ remains positive and the $I(V)$ characteristics is given by (Diamantini et al., 2020b)

$$I \propto V \exp\left(-\frac{\sigma_{\text{eff}}(T)L}{T}\right), \quad V < V_{\text{c1}} = \frac{\sigma(T)L}{2e}, \quad (17)$$

which, in the thermodynamic limit $L \rightarrow \infty$, implies an infinite resistance. This is the electric Meissner state of the superinsulator. When the applied voltage V reaches the critical value $V_{\text{c1}} = \sigma(T)L/2e$, the effective tension vanishes. This, however, does not entail complete destruction of the superinsulating state, the photon mass gap is still present. This means that, above this threshold, thin, long electric strings can penetrate the sample from one end to the other and current starts to pass. This is the transition from the

Fig. 6 Size dependence of the sheet resistance of a NbTiN film. In this logarithmic plot the *dashed straight line* corresponds to the usual activated behavior of a normal insulator. The largest samples show the hyperactivated behavior characteristic of superinsulation. The resistance of the shortest sample size 0.2 mm, however, saturates at the lowest temperatures, denoting a metallic behavior. For comparison, the string scale in this experiment was estimated as $d_s \approx 0.13$ mm. Reproduced from Diamantini MC et al. (2020b) Direct probe of the interior of an electric pion in a Cooper pair superinsulator. Communications on Physics 3: 142

electric Meissner state of a superinsulator, in which electric fields are completely expelled, to the mixed state in which electric flux tubes penetrate the sample. In this regime, the $I(V)$ characteristics acquire a power law form (Diamantini et al., 2020b),

$$I \propto (V - \sigma(T)L/2e)^{1+T_{\text{CBKT}}/16T}, \quad (18)$$

$$\text{at } V_{c1} < V < V_{c2} \equiv \frac{L}{2e} \left[\sigma(T) + \frac{T_{\text{CBKT}}}{2.718r_0} \right],$$

where T_{CBKT} is the charge BKT transition temperature. Above the second critical threshold V_{c2} , the photon mass vanishes, superinsulation is completely destroyed, and the system becomes a normal insulator.

The three possible states, Meissner state, mixed state, and normal insulator, are separated by two kinks in the $I(V)$ characteristics of a superinsulating material (Diamantini et al., 2020b), as shown in Fig. 7. For an infinite sample, the current $I(V)$ vanishes identically in the Meissner state, realized for $V < V_{c1}$.

Fig. 7 The two kinks in the $I(V)$ characteristics of a NbTiN film. For an infinite sample the $I(V)$ curve vanishes identically for $V < V_{c1}$, reflecting the electric Meissner state.

Fig. 8 Characteristic current time dependence upon application of a rectangular voltage pulse with amplitude $V = 0.155$ V and duration $50 \mu\text{s}$ (left panel) to a NbTiN film at the temperature of 20 mK. In the superinsulating state as compared to the same response of the normal insulator at 300 mK. The right panel displays the log-log plot of the current response time t_{sh} as function of the amplitude of the rectangular voltage pulse. The experimental data are shown by symbols. The solid lines present the fitting functions revealing the power law scaling of $t_{\text{sh}}(V - V_p)$ dependence. Reproduced from Mironov A-Y et al. (2022) Relaxation electrodynamics of superinsulators. Scientific Reports 12: 19918.

Dynamical exponents and the linear potential

The charge-hole potential in the superinsulating state can be measured directly by applying a voltage pulse and measuring the delay for current passage (Mironov et al., 2022). The results are presented in Fig. 8, in which the scaling of the current response time as a function of the pulse strength $(V - V_{\text{cl}})$ (here denoted as V_p) is shown for a rectangular pulse of strength V and duration $50 \mu\text{s}$ applied to a NbTiN film at 20 mK in the superinsulating state, and compared to the current response for the normal insulator at 300 mK.

The two kinks described in the previous section are again clearly visible and correspond to two different dynamical exponents μ in the scaling

$$t_{\text{sh}} \propto (V - V_{\text{cl}})^{-\mu}. \quad (19)$$

Consider two charges $\pm 2e$ of mass m bound by the linear potential $V(\mathbf{x}_1, \mathbf{x}_2) = \sigma|\mathbf{x}_1 - \mathbf{x}_2|$, where σ is the string tension of the confining electric string and $\mathbf{x}_i$ are the coordinates of the two particles. The critical value of the potential when current starts to pass is $V_{\text{cl}} = \sigma L$, with L being the sample length, corresponding to a configuration in which the two opposite charges reach the sample boundaries. In the center of mass coordinates, one can reduce the problem to a single particle of reduced mass $m/2$ at the origin, subject to the potential energy $U(r) = 2e\sigma r$, with r denoting the separation distance. A positive linear potential results in an attractive constant force $F_a = 2e\sigma = 2eV_{\text{cl}}/L$. An external potential V amounts to an additional repulsive force $F_r = 2eV/L$. The total acceleration of separation is thus $a = (2/m)F_{\text{tot}} = (4e/mL)(V - V_{\text{cl}})$. The corresponding equation of motion describing the separation distance of the charge-hole system is

$$r(t) = \frac{2e}{mL}(V - V_{\text{cl}})t^2. \quad (20)$$

Current starts to pass when charges of opposite sign reach the sample boundaries, that is when $r(t_{\text{cl}}) = L$. The delay for current passage is thus given by inverting Eq. (20),

$$t_{\text{cr}} = \sqrt{\frac{mL^2}{2e}}(V - V_{\text{cl}})^{-1/2}. \quad (21)$$

The observed dynamical exponent $\mu = 1/2$ is thus a direct confirmation of the linear potential binding charges of opposite sign.

Oblique superinsulators in 3D

Superconductors with emergent granularity also arise in three dimensions (Diamantini et al., 2021a). Similarly to their 2D counterparts, they are natural hosts for quantized Josephson vortices that comprise supercurrent rings spanning over adjacent granules in the same plane. The difference is that now since the current rings pile on top of each other to minimize the interaction energy, these Josephson vortices become 1D extended excitations. Since the resulting liner tension is low, nothing prevents the vortex cores to tear making them open and having magnetic monopole-antimonopole pairs at their ends. In the 3D case, magnetic

monopoles are no more instantons but become real, particle-like excitations. If the vortex tension vanishes, the quantized vortices turn into the unobservable Dirac strings (Dirac, 1931; Goddard and Olive, 1978): there is no energy price to pay to make one vortex go from one monopole to infinity and then return back to antimonopole. In this case magnetic monopoles form a Bose condensate, that is, 3D superinsulator (Diamantini et al., 2021c).

All the described properties of superinsulators, including the confining electric string between Cooper pairs, the Meissner state, and the nonlinear $I(V)$ curves can be derived, mutatis mutandis, as in the 2D case. The 3D superinsulators are characterized by dual London equations for the magnetic monopole current $\mathbf{j}_m$,

$$\begin{aligned}\partial_t \frac{\pi}{e} \mathbf{j}_m &= \frac{1}{\lambda_E^2} \mathbf{B}, \\ \nabla \wedge \frac{\pi}{e} \mathbf{j}_m &= \frac{1}{\lambda_e^2} \mathbf{E}.\end{aligned}\quad (22)$$

where the electric penetration depth is set by the photon mass, $\lambda_E = 1/m_{ph}$.

The new effect, arising exclusively in 3D, is the possible presence of the topological θ -term (Treiman et al., 1985)

$$S_\theta = \frac{\theta}{4\pi^2} \int d^4x \mathbf{E} \cdot \mathbf{B}. \quad (23)$$

in the electromagnetic action, giving rise to the so-called axion electrodynamics (Wilczek, 1987). If the gauge group is compact, the new parameter θ is an angle. The correct periodicity is 2π for fermionic systems and 4π for bosonic ones (Metlitski et al., 2013; Vishwanath and Senthil, 2013). The θ -term changes the character of superinsulators since it induces the electric charge $\theta/2\pi$ on magnetic monopoles (Witten, 1979) which become *dyons*, the particles carrying both electric and magnetic charge (Goddard and Olive, 1978). In the presence of the θ -term one arrives at the *oblique superinsulator*, a Bose condensate of both electric and magnetic charges, in which the corresponding oblique London equations hold:

$$\begin{aligned}\partial_t \frac{\pi}{e} \mathbf{j}_m &= \frac{\Lambda^2}{4e^2} \left(\mathbf{B} + \frac{2e^2}{\pi} \frac{\theta}{2\pi} \mathbf{E} \right), \\ \nabla \wedge \frac{\pi}{e} \mathbf{j}_m &= \frac{\Lambda^2}{4e^2} \left(\mathbf{E} - \frac{2e^2}{\pi} \frac{\theta}{2\pi} \mathbf{B} \right).\end{aligned}\quad (24)$$

Here, Λ denotes the gap energy scale. Combining these equations with the (static) Ampère equations in the presence of the magnetic charge

$$\begin{aligned}\nabla \wedge \mathbf{B} &= 2e \mathbf{j}_e, \\ \nabla \wedge \mathbf{E} &= -\frac{\pi}{e} \mathbf{j}_m,\end{aligned}\quad (25)$$

and using the fact that the electric current is $\mathbf{j}_e = (\theta/2\pi)\mathbf{j}_m$ since it is carried by charged magnetic monopoles one obtains (for sourceless currents)

$$\left(\nabla^2 - \frac{1}{\lambda_\theta^2} \right) \mathbf{j}_e = 0, \quad (26)$$

where

$$\lambda_\theta = \frac{\pi}{e\Lambda} \frac{1}{\sqrt{\left(\frac{\pi}{2e^2}\right)^2 + \left(\frac{\theta}{2\pi}\right)^2}}. \quad (27)$$

Currents are screened in the interior of the dyon condensate and survive only in the surface strips of the width set by the oblique penetration depth λ_θ . While in normal superinsulators the penetration depth increases in the strong coupling limit, the contrary is true for oblique superinsulators, where for $e \rightarrow \infty$ we have $\lambda_\theta \rightarrow 0$. One can show that in this limit, oblique superinsulators form a topological state of matter in which only edge states survive while the bulk charges are frozen by the diverging gap (Diamantini et al., 2021b). The θ -term residing on closed manifolds is equivalent to the Chern–Simons term on the boundary (Treiman et al., 1985). This induces statistical transmutations for the surviving edge states (Wilczek, 1990). In particular, for $\theta = 2\pi$, the edge states become symmetry-protected charge $2e$ fermions and thus are expected to behave as an ideal Fermi liquid, with the resistance scaling as the square of temperature. The experiments reported precisely this $R \propto T^2$ resistance behavior in the pseudogap state of high- T_c superconductors (Zhou, 2021). This observation in conjunction with the nematicity and magnetoelectric effects observed in the pseudogap state, set the base for putting forth the proposal that the pseudogap state, proclaimed in Zhou (2021) as an unanswered issue, is actually the oblique superinsulator (Diamantini et al., 2021b).

The role of disorder

The first quantitative descriptions of the superinsulating state were derived in the context of JJAs (Diamantini et al., 1996; Fistul et al., 2008) and revealed that, in this context, the tuning parameter driving the SIT is $g \simeq E_J/E_C$ that is, the relative strength of the Josephson coupling and the Coulomb interaction. At the same time, experimentally, superinsulation was discovered

(Baturina et al., 2007) by driving a TiN film across the SIT via tuning the room temperature sheet resistance $R_{\square}(T_{\text{Room}})$, which is a measure of disorder. Indeed, disorder enhances the Coulomb interaction by reducing the charge screening (Finkel'shtein, 1987). The main parameter driving the SIT is the relative strength of the Coulomb interaction: disorder is indeed one of the possible ways to affect this strength, as is the thickness of the film or an applied magnetic field.

A widespread view at the dawn of SIT studies was that disorder plays also another role, governing the structure of the phase diagram near the SIT via Anderson localization of the Cooper pairs (Fisher, 1990a; Fisher et al., 1990b) or its interacting version, referred to as many-body localization (Altshuler et al., 2006; Basko et al., 2007; Altshuler et al., 2009), see Sacépé et al. (2020) for a review. A consistent theory of the SIT (Diamantini et al., 2020a, 2021a) demonstrates, however, that localization does not play a role in the critical vicinity of the SIT because, on one hand, of the dominance of topological interactions in the intermediate Bose metal state and, on the other hand, the presence of long range linear Coulomb interactions in the superinsulating state. Exactly as in the quantum Hall effect (QHE), localization can help to pin the quasi-particles forming around the topological ground state (Pu et al., 2021) corresponding to the Bose metal, although, strictly speaking not even this is necessary, neither for the formation of plateaus in the QHE (Kim and Kivelson, 2021) nor for the emergence of the topological Bose metal phase (Diamantini et al., 2021a). On the other side, many-body localization does not survive linear interactions, not even in 1D, where they are kinematic (Nandkishore and Sondhi, 2017; Akhtar et al., 2018), and may become effective when only short-range interactions are present. Only after one has identified the correct neutral physical states in the spectrum and only short-range interactions are left, can one even speak of localization.

The observation of two kinks (rather than only one), see Fig. 6, in the $I(V)$ curves in the superinsulating state (Diamantini et al., 2020b), is a strong experimental evidence that Cooper pairs are confined by Polyakov's strings, rather than localized by disorder. Localization by disorder is further strongly disfavored by the measurement of a linear potential between charges of opposite sign in the superinsulating state (Mironov et al., 2022). Notably, the confinement by this linear potential induces breaking of thermalization and ergodicity. These phenomena are typically associated with many-body localization in the presence of disorder (James et al., 2019; Mazza et al., 2019). Note that while the many-body localization phenomenon is far from being established in 2D and 3D, the phenomena associated with it are straightforward and typical consequences of the established existence of the confinement phase. Therefore, while disorder may appear as an important tuning parameter for the SIT, it is irrelevant in the renormalization group sense in the critical vicinity of the SIT, since it does not influence the character of the phases emerging near the superconductor-superinsulator transition. The interpretation of this effect as a finite-temperature insulating behavior due to many-body localization proposed in Ovidia et al. (2015) is thus disfavored by recent experimental evidences.

Conclusion

We have shown that condensed matter systems that admit magnetic monopoles lead to a material realization of the S duality under exchange of electric and magnetic fields and charges. Under this duality, a superconductor is mapped into a superinsulator, a phase in which the system exhibits an infinite electric resistance (even at finite temperatures). Contrary to the superconducting phase, where vortices experience logarithmic interactions, in superinsulators charges are bound into neutral pairs by linear potentials due to the "endogenous disorder" created by the monopoles. Superinsulation has been experimentally detected in TiN, InO, NbTiN, and NbSi films. In bulk materials, a particular, "oblique" version of superinsulation may be realized in the pseudogap state of high-temperature superconductors.

EDITOR-IN-CHIEF BIOGRAPHY

Tapash Chakraborty is a retired professor of physics from the University of Manitoba, Canada, where he was also the Canada Research Chair in Nanoscale Physics (2003–17). His research focus has been on many-body theories of various quantum materials, such as nuclear matter, helium liquids, and electron-hole liquids, that he studied under the tutelage of late Professor Manfred Ristig, at the University of Köln (1979–81). Just a year after the discovery of the fractional quantum Hall effect, he (working with his coworkers) demonstrated that electron–electron interactions could actually lead to quantum Hall states with nontrivial spin configurations, and that the low-lying excitations could be described as “spin-reversed quasiparticles.” This prediction motivated much experimental work from laboratories around the world, as a result of which the concept of spin-reversed quasi-particles was established.

Similarly, his work on the quantum Hall states in double layer systems has received much attention from the community. Furthermore, Dr. Chakraborty (working with Dr. P. Maksym and others) made pioneering contributions to the many-electron theory of quantum dots. Dr. Chakraborty has also contributed to the theory of electronic properties of various nanoscale systems, such as spin-orbit coupled quantum dots, quantum rings, and single- and double-layer graphene (primarily with Dr. V. Apalkov). He has authored many books and reviews: the book with Dr. Pietiläinen on the quantum Hall effect and the single-authored book on quantum dots have become standard references in their respective fields.

INTRODUCTION

Electrons in orbits contained by the quantum,
And atoms conjoined by the dipolar force,
Gravity balanced by pressure
And flap of a wing.
Here, I remember the angles and curves,
Calculus, I learned it all –
Each bird bit and moon fracture
Fixed by the symmetries,
Airborne and airless, aloft.

– Alan Lightman: *Song of Two Worlds*

Condensed matter physics (CMP) is the largest discipline in physics, involving a wide variety of interesting concepts and challenges. To quote [Leggett \(1992\)](#), CMP embraces topics “as diverse as traditional solid-state physics, neutron stars and the physics of biological matter.” He further added that, by a liberal definition “just about all of physics outside atomic, nuclear and particle physics and cosmology” fall in this vast enterprise¹. One of the primary goals of CMP is to explore the fundamental properties of matter—solids, liquids or gasses—comprising a large number of *interacting* constituent particles ([Laughlin and Pines, 2000](#)). The quantum-mechanical nature of these many-body systems makes condensed-matter highly nontrivial, sometimes counterintuitive and even astonishing. Superconductivity and the fractional quantum Hall effect (FQHE) naturally fall within that category. In fact, for the past four decades, the quantum Hall effects (QHEs) have been the epitome of elegant CMP ([von Klitzing et al., 2020](#)). Our fundamental system of units has been redefined following the discovery of the QHE when the “von Klitzing constant” $R_K = 25,812.8074593045 \, \Omega$ came into being ([von Klitzing, 2019](#); [Nawrocki, 2019](#)). Observation of the QHE in graphene² was crucial in determining the Dirac nature of charge carriers there (see for example, [Jiang et al., 2007](#)).

Another effect that outwardly resembles the QHE but is conceptually quite different is the FQHE, which is a quintessential manifestation of electron correlations governed by the Coulomb interaction ([Störmer, 1992](#); [Eisenstein and Stormer, 1990](#)). To explain this fascinating effect, [Laughlin \(1983\)](#) introduced his eponymous wave function that not only provided the foundation for understanding the effect but also triggered a new wave of ideas with impact far beyond the realm of CMP³. Who would have imagined that a large collection of interacting electrons confined on a plane in a perpendicular magnetic field would result in elementary excitations (quasiholes and quasiparticles) ([Chakraborty and Pietiläinen, 1988, 1995](#); [Halperin, 1983](#); [Clark and Maksym, 1989](#)) carrying fractional electron charge and obeying the exotic exchange statistics of anyons ([Halperin, 1984](#); [Arovas et al., 1984](#))? These quasiparticles and quasiholes of the Laughlin state still remain an enigma ([Laughlin, 1984](#); [Chakraborty, 1985](#); [Morf and Halperin, 1986](#)). Fractional statistics is a truly path-breaking concept in CMP that was introduced by [Leinaas and Myrheim \(1977\)](#), and has been recently confirmed experimentally ([Bartolomei et al., 2020](#); [Nakamura et al., 2020](#)).

Much of the history of CMP can be viewed as a series of paradigm shifts⁴. The field evolved rapidly through frequent ground-breaking discoveries that challenged existing paradigms and opened up new applications, and this evolution is expected to continue ([Leggett, 2018](#); [Cohen, 2008](#)). For example, our current understanding of

¹Interestingly, some similarities do exist between the mathematical frameworks that describe low-temperature CMP and early-universe cosmology. See [Kibble and Srivastava \(2013\)](#).

²An isolated single layer of graphite consisting of carbon atoms bonded together in a hexagonal structure. See, e.g., [Abergel et al. \(2010\)](#).

³For example, an important aspect of Laughlin's theory is its seamless concinnity of classical plasma physics and the planar electron gas that has inspired others to use a similar approach to quark-gluon plasma ([Lu, 2022](#)).

⁴A detailed exposition of the meaning and examples of “paradigm shifts” (Kuhn-type) can be found in [Leggett \(2018\)](#).

the FQHE required deep mathematical analysis and a wide range of experimental exploration, which revealed a treasure trove of unique phenomena that are yet to be fully understood or explained. Other studies of electron correlations in low spatial dimensions have ushered in many groundbreaking notions, such as Pfaffian states, Majorana fermions in condensed matter, Chern insulators, and topological quantum materials that promise a fault tolerant means to perform quantum computation. The presence of incompressible FQHE states in monolayer graphene (Apalkov and Chakraborty, 2006), bilayer graphene (Apalkov and Chakraborty, 2010, 2011), and double-layer graphene (Liu et al., 2019) has demonstrated the robustness of the effect, and provides invaluable insight into the nature of this effect.

The dynamics of an electron in a periodic potential subjected to a perpendicular magnetic field has been an intriguing problem for more than half a century (Obermair and Wannier, 1976; Osadchy and Avron, 2001)⁵. Within the nearest neighbor tight-binding description of the periodic potential the electron energy spectrum is described by the Harper equation (Harper, 1955). Numerical solution of this equation (Hofstadter, 1976) has revealed that the applied field splits the Bloch bands into subbands and gaps. As the field is varied, the splitting of band continues indefinitely, leading to bands within bands within bands. When plotted as a function of the magnetic flux per lattice cell, the energy spectrum depicts a *fractal* pattern (a self-similar pattern that repeats at every scale) and is known in the literature as Hofstadter's butterfly because of the resemblance of the pattern to butterflies⁶. Observation of the butterfly spectra in real systems is an arduous task. For example, in ordinary crystalline lattices, the required magnetic field to see the butterflies exceeds 1000 Tesla, which is far beyond the reach of present-day technology. Graphene seems to be the ideal system in the quest of those fractal butterflies (Weiss, 2013). It is interesting to note that a mathematical solution of the Harper equation, in contrast to the numerical solution mentioned above, remained a challenging problem (the so-called Ten Martini Problem) for mathematicians until it was solved (Avila and Jitomirskaya, 2006) in 2006.

Magnetism has been known to mankind since ancient times, and it remains a major topic in CMP. The road to understanding magnetism has been long and tortuous. At various times in history, magnets were claimed to have the healing power to cure a myriad of ailments that included epilepsy, arthritis, gout, and baldness. Magnets were the prime ingredients for the "elixir of life" by Paracelsus (1493–1541). Then there was the healing process of "animal magnetism" proposed by Franz Anton Mesmer (1734–1815) (mesmerism)⁷, which was famously mocked in Mozart's *Così fan tutte* (Stephoe, 1986). Our current understanding of magnetism is deeply rooted in quantum mechanics as Van Vleck explained (Van Vleck, 1978): "Quantum mechanics is the key to understand magnetism. When one enters the first room with this key there are unexpected rooms beyond, but it is always the master key that unlocks each door." For centuries, the magnetism of certain rocks and metallic iron was only used for the practical purposes of direction finding, particularly navigation with a compass. Motors, generators, and electrical distribution networks appeared only in the 19th century after the discovery of the deep connection between electricity and magnetism. Magnetic order is a collective phenomenon akin to superconductivity and superfluidity that involves a very large number of particles. The rich variety of magnetically ordered states in solids, not only ferromagnetism but also antiferromagnetism, ferrimagnetism, and a range of noncollinear structures, was confirmed only in the middle of the 20th century, with the availability of neutron beams in research reactors. A range of new magnetic materials are taking their place as active layers in thin film sensors and memory devices (Baltz et al., 2018). Besides information storage (Blundell, 2001), important technical applications include magnetic resonance imaging (MRI) and the use of magnetic nanoparticles in medicine.

Many outstanding discoveries in magnetism and magnetic materials have resulted in rapid advances in information storage technology. Over the last two decades spintronics has emerged as an important field of research both from the point of view of fundamental science and advanced technological applications (Yamaguchi et al., 2021; Pinarbasi and Kent, 2022). The giant magnetoresistance (GMR) effect, the spin Hall effect, and the spin galvanic effects are typical examples of developments in the field. Spintronics aims at understanding how the spin degree of freedom of the electrical carriers can be controlled in order to obtain devices with new functionalities and better performance. This endeavor often combines concepts from different aspects of condensed matter systems, giving the topic a fascinating interdisciplinary flavor. Spintronic phenomena are now being studied in an impressive range of different materials ranging from metals to half-metals to semiconductors, graphene and other two-dimensional systems such as transition metal dichalcogenides.

⁵For a recent review on butterflies in graphene, see for example Chakraborty and Apalkov (2015).

⁶However, as one of the authors of this Encyclopedia has (somewhat humorously) pointed out, this butterfly has Lebesgue measure zero, that is, it cannot fly!.

⁷A wonderful account of the use of magnetism in medicine since ancient times can be found in Mourino (1991).

The GMR effect and the related tunnel magnetoresistance effect (TMR) found their first commercial use in magnetic field sensors for hard-disk read-heads, before broadening their field of application to include magnetic sensors for the automobile industry, solid-state compasses, biosensors, and nonvolatile magnetic memory (Hartmann, 2000). The ability to manipulate the magnetic state of ferromagnetic structures led to initial developments in spintronics, where the spin direction was controlled by externally applied magnetic fields. However, the push for downscaling and faster timescales has prompted research advances in the past decade where the manipulation of magnetic configurations is achieved by local electric currents (the spin torque effect) (Brataas et al., 2012; Locatelli et al., 2014). In recent years, various novel concepts, such as chiral spintronics, skyrmionic spin textures, and magnetic domain walls in spintronics, have been actively pursued. The rate of progress in spintronics is truly astounding (Editorial, 2022).

In the past century, superconductivity has raised many theoretical challenges and triggered numerous technical developments. Discovered in mercury in 1911, this unique phenomenon occurs when the electrical resistance of many metals and alloys drops to zero when cooled below about 4 K, the temperature of liquid helium. More significantly, the material expels magnetic flux and becomes perfectly diamagnetic. Superconductivity has been adopted or evaluated for a wide range of technical applications (Rogalla and Kes, 2012). These include electric power generation, electric power transmission, high-speed maglev transportation, and ultra-strong magnetic field generation in high-resolution MRI and other nuclear magnetic resonance (NMR) systems. Interestingly, it took almost 50 years after the original discovery for the phenomena to be explained by the BCS theory (Tinkham, 2004) of reciprocal-space electron pairing, via the electron–phonon interaction. This electron–phonon mediated superconductivity became known as “conventional superconductivity” after the discovery of “high-temperature superconductivity” (Müller and Bednorz, 1987) at liquid nitrogen temperatures in tetragonal copper oxides in 1986. This threw open a new challenge to explain the properties of strongly correlated *anisotropic* electronic systems. Further new classes of superconductors that remain to be properly understood include the iron-based pnictides discovered in 2008 (Hosono et al., 2018). Recently, a two-dimensional superlattice made from a twisted bilayer of “magic angle” graphene was found to exhibit unconventional superconductivity (Cao et al., 2018), driven by electron–electron interactions.

The phenomenon of spontaneous symmetry breaking (SSB) is ubiquitous in physics, and plays a fundamental role in CMP, particle physics, and even in cosmology. A classic illustration of SSB being Heisenberg’s 1928 paper on ferromagnetism (Heisenberg, 1928). It is responsible for various collective modes, such as the famous Nambu-Goldstone (NG) and Higgs modes. Named by Baker and Glashow (Baker and Glashow, 1962), SSB corresponds to the case where the ground or lowest-energy state does not have the symmetry of the underlying dynamics. Instead, multiple degenerate ground states are available and the symmetry breaking is *spontaneous* because it is not clear, a priori, which one of those ground states will be chosen. In this well-trodden territory a simple analogy of this abstruse concept given by A. Salam is illuminating (CERN, 1977): “Imagine a banquet where guests sit at round tables. A bird’s eye view of the scene presents total symmetry, with serviettes alternating with people around each table. A person could equally well take a serviette from his right or from his left. The symmetry is spontaneously broken when one guest decides to pick up from his left and everyone else follows suit.” Over the years, development of the concept of SSB has taken a circuitous route (Gaudenzi, 2022): “from the land of particle physics to the physics of many bodies (solids and nuclei), from there to the province of superconductivity, and from the latter back to particle physics” SSB’s significance extends beyond the physics of the Higgs boson to the study of low-energy phenomena such as superconductivity, superfluidity, magnetism, and others. Historically, the particle physics community has been guided by this exploration in their quest to understand and discover particles like the Higgs boson. More to the point, when a continuous symmetry is spontaneously broken, a gapless mode, the NG mode, appears which governs the low-energy behavior of the system. As an example, in a solid, the acoustic phonon is the NG mode associated with translational symmetry breaking and determines the behavior of the specific heat at low temperature (the Debye T^3 law). Recently, signatures of Higgs and Goldstone modes have been proposed to exist in a perovskite oxide (Marthinsen et al., 2018), in other crystalline structures (Vallone, 2019), and also in various other quantum systems (Léonard et al., 2017). On a lighter note, it is the symmetry breaking that is claimed to have prevented the fabled donkey (Weintraub, 2012) in the parable by Jean Buridan (1300–50) from dying of starvation (Fubini, 1974).

Common to the theoretical descriptions of these phenomena across CMP and high-energy physics is Quantum field theory (QFT). QFT was originally developed to describe the fundamental processes in high-energy physics, but has now become a valuable tool to address problems across physics, in particular, in CMP (Fradkin, 2013; see also, Mustafa, 2023), statistical physics, modern quantum chemistry, and even in

pure mathematics (Folland, 2008). Advances in our understanding of strongly correlated electron systems in CMP such as high-temperature superconductivity and the FQHE have been aided by the QFT. It has facilitated the treatment of spontaneous symmetry broken states, such as superfluids. Interestingly, many of the conceptual developments in CMP have, in return, had a reciprocal impact in QFT. A spectacular example being Nambu's work in dynamical symmetry breaking (Weinberg, 1986; Nambu, 2009) in particle physics, based on the BCS theory of superconductivity.

A glass is a noncrystalline solid obtained by quenching a liquid. It has a liquid-like structure, but a transition from liquid to solid behavior occurs on cooling. It may have one of a continuum of possible ground states that exhibit frozen-in liquid-like disorder. The term “spin glass” was coined by B.R. Coles (Mydosh, 1993) in 1970 for a diluted magnetic material with frozen-in paramagnetic-like spin disorder where the magnetic moments interact with randomly varying positive or negative exchange interactions leading to a multitude of possible ground states with different, random orientations of the spins. As in a normal glass, the energy barriers between the continuum of metastable states prevent it from ever reaching equilibrium. This phase of condensed matter has been an important and productive area of research. Spin-glass models are conceptually simple, but embody sophisticated physics. These models have become a paradigm for the solution of complex optimization problems (Mézard, 2022): much like the undulating flight patterns of starlings around the skies over Rome (Parisi, 2023). After cooling from the paramagnetic phase, the spin glass remains out of equilibrium, and it slowly evolves. This aging phenomenon corresponds to the growth of a “spin-glass order” parameter, whose correlation length can be measured (Joh et al., 1999). A cooling temperature step during aging causes a partial “rejuvenation,” while the “memory” of previous aging is stored and can be retrieved (Refregier et al., 1987; Bouchaud et al., 2001). Many glassy materials present aging, and rejuvenation and memory effects can be found in other cases, but they are usually less pronounced. Numerical simulations of these phenomena are under active investigation using custom-built computers (Baity-Jesi et al., 2023; Vincent, 2023). A general understanding of glassy systems, to which spin glasses bring some special insight, is being pursued. It was realized decades ago that the physics of spin glasses has deep connections with the behavior of complex biological systems. In fact, spin-glass type states in neural network models offer interesting insights into states of high and low brain activity, as observed in mammals (Recio and Torres, 2016). These analogies are potentially useful for applications in fields such as robotics and artificial intelligence (AI) (Andriuschenko et al., 2022).

One of the most spectacular phenomena in CMP, discovered in the last century, was Bose-Einstein condensation (BEC). This macroscopic quantum phenomenon had its genesis in the work of Satyendra Nath Bose (Bose, 1924; Blanpied, 1972; Tomczyk, 2022) (whose name is forever associated with bosons), and has fascinated physicists for decades, ever since the first observation of this exotic state of matter in an ultracold gas of rubidium atoms (Georgescu, 2020). Among the advances made in this field, we highlight only a few: simulation of correlated electron states, such as the FQHE state and a bosonic analog of the Laughlin state, and the famous BEC-BCS crossover from a BEC to a BCS superfluid of weakly bound Cooper pairs, as the interparticle interaction strength is varied. Noteworthy is the recent measurement of the dynamic structure factor in an ultracold Fermi gas of lithium-6 atoms in the “unitary” limit, where a linear phonon mode for low momentum transfer can be clearly discerned (Biss et al., 2022). Perhaps such a method might one day shed light on the Laughlin quasiparticle gap and the collective modes that are still largely unresolved (Chakraborty and Pietiläinen, 1988, 1995; Halperin, 1983; Clark and Maksym, 1989).

Liquid helium, ^4He , and the less common isotope ^3He are unique quantum systems (Volovik, 2009). They remain liquid even at absolute zero temperature, a direct manifestation of Heisenberg's uncertainty principle and zero-point energy. The light mass of helium atoms and their weak interatomic attraction leads to a substantial zero-point kinetic energy and the system remains in the liquid state at ambient pressure. Solidification occurs when a pressure of about 25 MPa is applied. The different quantum statistics of the two helium isotopes (^4He is a boson while ^3He is a fermion) are responsible for the different physical characteristics of the two systems. Microscopic approaches to understand the ground state and low-energy excitations of the liquid state have occupied researchers for many decades (see for example, Ristig and Clark, 1976; Lam et al., 1977). These highly correlated quantum fluids have been established as systems where the efficacies of different many-body theories can be tested (Kallio and Smith, 1977; Lantto et al., 1977). These systems have been described as Ariadne's thread in this Encyclopedia, where the strongly interacting constituent particles are treated by a variety of ingenious theoretical and experimental approaches. Interestingly, liquid helium has been proposed to be a medium to design multiexcitation detectors to probe *dark matter* (Schutz and Zurek, 2016) in the keV mass limit. Although this looks far afield from CMP, the interface between CMP and high-energy particle physics could inspire new horizons in CMP, as discussed earlier.

CMP also has an enormous impact on our daily lives with unceasing technological innovation stemming directly from the advances in CMP research. It is also closely associated with the progress of our understanding of materials science and mechanical, chemical, and electrical engineering that deals with properties of novel materials and devices. As some authors have very aptly pointed out (Chaikin and Lubensky, 1995): The use and understanding of matter in its condensed (liquid or solid) state have gone hand in hand with the advances of civilization and technology since the first use of primitive tools. So important has the control of condensed matter been to man that prehistoric ages—the Stone Age, the Bronze Age, the Iron Age—are named after the material dominating the technology of the time. In fact, modern civilization is entirely dependent on our deep understanding and practical use of materials, old and new: Steel, glass, and concrete have shaped our modern living with comfort, health, longevity, and material wealth. All around us, from a tiny paper clip to giant skyscrapers, from jet planes to modern medicines, and the ubiquitous plastics that are integrated into nearly all aspects of human life, are testaments to our control over the myriad behavior of materials (Miodownik, 2014). Today, a large number of materials are designed by using principles of quantum mechanics (Freeman, 2002).

The Silicon chip that launched the information age is a great example of the effect of CMP on our daily lives. The scaling of transistors down to the nanometer range has enabled them to be embedded in greater numbers in the all-pervasive electronic devices that have transformed every facet of life all around the world. The transition from room-size to pocket-size computers with ever increasing computational power and memory, that occurred in only a few decades, epitomizes the unrelenting progress made in this direction. Advances in nanoscale research have opened the door to exploration of the natural world at the ultra-small scale (Chakraborty, 2022), with the potential to shape our future world.

Quantum dots (QDs), the quasi-zero-dimensional electron systems, are one of the most extensively studied nanostructures in the past three decades. They represent the ultimate reduction in dimensionality of a semiconductor device. Here the electrons are confined (either electrostatically or structurally) in all three directions and occupy spectrally sharp energy levels similar to those found in atoms (Chakraborty, 1999), hence the popular moniker *artificial atoms* (Maksym and Chakraborty, 1990). QDs and other similar nanostructures (Chakraborty, 2003) offer a rich variety of fundamental phenomena that result from manipulation of single electrons (single electronics) or single spins at the nanoscale. The study of interacting electrons in a QD requires large-scale numerical computations involving matrices of dimensions in the millions (“monster matrices”) (Chakraborty and Pietiläinen, 2005; Pietiläinen and Chakraborty, 2006). QDs are also thought to have vast potential for future technological applications. One prominent example being quantum cryptography where the QDs are used in single photon emitters (Nowak et al., 2014), and in single photon detectors (Shields et al., 2000). Quantum cryptography, in turn, forms the basis of the *quantum Internet* (Liao et al., 2018). Other applications include lasers, and spintronics in quantum computing, entertainment industry (Bourzac, 2013), and even in biology (Bruchez and Holz, 2007).

Research in recent years has increasingly revealed that quantum phenomena are also ubiquitous in the natural world (Ball, 2011). They govern how birds are able to navigate around the globe using Earth’s magnetic field or how plants use photosynthesis to harvest sunlight for conversion to chemical energy. All depend on subtle quantum effects that are now coming to light, thereby ushering the topic of quantum biology into CMP. Deoxyribonucleic acid (DNA), the molecule responsible for storage of genetic information in the cells of all living organism, is entrusted with the task of preserving, copying, and transmitting information that are necessary for living beings to grow and function. It is often referred to as the body’s hereditary material as DNA is replicated and transmitted from parents to their offspring. This “molecule of life” was discovered in 1869 by Friedrich Miescher in Tübingen, Germany, who called it “nuclein,” as it was isolated from the nucleus of white blood cells (Dahm, 2005; Thess et al., 2021). It took more than eighty years from that momentous event, to discover that DNA has a right-handed double-helix structure with appropriate base pairing (Watson and Crick, 1953; Klug, 2004). That discovery was so important that it has been compared with the discovery of the atomic nucleus in physics (Frank-Kamenetskii, 1997). Understanding the structure of the atom heralded quantum physics, while understanding of the structure of DNA brought forth the field of molecular biology.

DNA has several remarkable properties that make this molecule a prime candidate for nano-electronic materials (Chakraborty, 2007). These include molecular recognition and the ability to self-assemble via the complementarity of the base sequences on the two strands, which means that DNA can be integrated error-free in current semiconductor technology. DNA can also detect information about its own integrity that can trigger its eventual repair mechanism. All these properties are perfectly suitable for developing nanoscale electronics involving DNA

(Taniguchi and Kawai, 2006). Despite the promise of harnessing biology to realize integrated molecular electronics remains fascinating, much work remains to be done to make it a reality (Braun and Keren, 2004).

Protein molecules play a vital role in all living organisms. They are described as Nature's robots (Tanford and Reynolds, 2001) because for every imaginable task required in a living organism, and for every step of that task, there is a protein designed to carry it out. These proteins are even programmed to know when to turn on or off. Just as the twenty-six letters in the alphabet can spell out hundreds of thousands of words, there are twenty different naturally occurring amino acids that can be combined into many more different proteins than there are atoms in the known universe! Protein's biological function is determined by its unique and native three-dimensional structures that are characteristic of individual proteins (Gomes and Faísca, 2019; Echenique, 2007). The question of how proteins fold to their unique, compact, and highly organized functional states has remained an enduring challenge ("The protein-folding problem") (Chan and Dill, 1993; Dill and MacCallum, 2012; Wolynes and Eaton, 1999). Recently, there has been a tremendous development in this area of research. In November 2020, an AI program called AlphaFold, designed to tackle the problem of protein folding, predicted the three-dimensional structures of almost every protein known to science—about 200 millions in all (Jumper et al., 2021). AlphaFold uses a machine learning methodology to bring together information from preexisting knowledge of protein structures, and other geometric and physical constraints to predict protein structures. While this has been heralded a watershed moment in structural biology (Perrakis and Sixma, 2021), there are many key questions that AlphaFold cannot address yet. These include aspects of protein behavior that cannot be understood from a static structure, such as how proteins respond to their environment or how intrinsically disordered proteins actually are organized. Some authors (Nasser et al., 2021) have likened it to solving a crime story: while AlphaFold presents a snapshot in time, the question about how we get there remains unanswered. Biological systems have developed elaborate mechanisms to ensure that proteins fold correctly, or otherwise, they are detected and degraded before any serious harm can result to the host organism. However, protein misfolding does happen and that misfolding in the cell is linked to an array of diseases, including cancers, cardiovascular disease, type II diabetes, and numerous neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Huntington's disease. NMR spectroscopy has been an important technique to study protein folding where valuable insights are gained into many aspects of the folding process (Jane Dyson and Wright, 1996).

In this Encyclopedia, we strive to present a taste of all the developments in CMP described above (and much more), written by experts in the field. We are keenly aware that many important and interesting topics are not covered here. However, that is not for want of trying. As some authors had rightly pointed out (Hoddeson, 1992): The field is huge and varied and lacks the unifying features beloved of historians, neither a single hypothesis or set of basic equations underpin the field, as in quantum mechanics or relativity theory, nor a single spectacular and fundamental discovery such as uranium fission for nuclear technology or the structure of DNA for molecular biology. CMP owes what unity it has simply to a common concern with solid and liquid materials. This encompasses such a large range of theories and methods that the field resembles a confederation of interest groups rather than a single entity. Clearly, the task of collecting everything in one place is a monumental endeavor, but we do hope that our compilation of a large number of chapters in this five-volume work, covering a broad range of in-depth descriptions of varied phenomena in CMP will be a treasured source of facts and ideas for the community.

It is undeniably true that there would have been no Encyclopedia without the extraordinary contributions of the large number of authors whose valuable time and efforts brought this project to fruition. My sincere thanks to all of them. I also wish to extend my deep appreciation to the staff at Elsevier for their skillful handling of this huge project. The cover image was created by Hong-Yi Chen from National Taiwan Normal University. The image below was created by Elisabetta Collini, one of the authors. My deepest appreciation to them for taking the time to do this work. Finally, my sincere thanks to the Section editors, Vladimir Fomin, Ana Sanchez, Roberto Raimondi, Hideo Aoki, Rudolf Römer, and Robert Blick for the effort they all expended, that has contributed to the success of this venture. Special thanks go to Vladimir Fomin and Ana Sanchez for securing a large share of the chapters and for their enduring help in providing valuable advice and support to bring the project to fruition. Thanks are also due to many of my friends and colleagues, in particular, Michael Coey, Jürg Fröhlich, Sinéad Griffin, Peter Maksym, Eric Vincent, and Jakob Yngvason for their careful and critical reading of the introduction.

LIST OF CONTRIBUTORS FOR VOLUME 3

Kyosuke Adachi

RIKEN Center for Biosystems Dynamics Research, Kobe, Japan; RIKEN Interdisciplinary Theoretical and Mathematical Sciences Program, Wako, Japan

Jimmie Adriaola

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

M Agio

Università degli Studi di Pavia, Pavia, Italy

Farzin Akbar

Micro- and NanoBiomedical Engineering Group (MNBE), Institute for Integrative Nanosciences, Leibniz Institute for Solid State and Materials Research (IFW), Dresden, Germany

M-C Amann

Technische Universität München, Garching, Germany

LC Andreani

Università degli Studi di Pavia, Pavia, Italy

SN Aqida

Automotive Engineering Centre, Universiti Malaysia Pahang, Pekan, Pahang, Malaysia

Giorgio Baccarani

Department of Electrical Electronic and Information Engineering (DEI), and Advanced Research Center on Electronic Systems E. de Castro (ARCES), University of Bologna, Bologna, Italy

M Basini

Department of Physics, Stockholm University, Stockholm, Sweden

J Bass

Michigan State University, East Lansing, MI, United States

K Behnia

Ecole Supérieure de Physique et de Chimie Industrielles, Paris, France

Antonio Bianconi

Institute of Crystallography, CNR, Rome, Italy; RICMASS Rome International Center for Materials Science, Rome, Italy

Christopher Bolton

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

D Bossini

Department of Physics and Center for Applied Photonics, University of Konstanz, Konstanz, Germany

K Bowman

Purdue University, West Lafayette, IN, USA

Stéphane Brûlé

Aix-Marseille Université, CNRS, Centrale Marseille, Institut Fresnel, Marseille, France

Gaetano Campi

Institute of Crystallography, CNR, Rome, Italy

A Cano

Université Grenoble Alpes, CNRS, Institut Néel, Grenoble, France

David Castellanos Robles

Micro- and NanoBiomedical Engineering Group (MNBE), Institute for Integrative Nanosciences, Leibniz Institute for Solid State and Materials Research (IFW), Dresden, Germany

Tapash Chakraborty

Department of Physics, Brock University, St. Catharines, ON, Canada; Department of Physics and Astronomy, University of Manitoba, Winnipeg, MB, Canada

JR Chelikowsky

University of Texas at Austin, Austin, TX, USA

Kikuo Cho

Emeritus of Osaka University, Kobe, Japan

Alexander T Clark

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

John W Clark

Department of Physics, Washington University, St. Louis, MI, United States; Centro de Investigação em Matemática e Aplicações, University of Madeira, Funchal, Portugal

Rosa Córdoba

Institute of Molecular Science, University of Valencia, Paterna, Spain

Francisco AG de Lira

Department of Physics, Federal University of Maranhão, São Luís, Maranhão, Brazil

Alexander L Efros

Center for Computational Material Science, Naval Research Laboratory, Washington, DC, United States

Christoph Eigen

Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom

NG Einspruch

University of Miami, Coral Gables, FL, USA

SR Elliott

University of Cambridge, Cambridge, United Kingdom

Stefan Enoch

Aix-Marseille Université, CNRS, Centrale Marseille, Institut Fresnel, Marseille, France

Leonardo Fallani

Department of Physics and Astronomy, University of Florence, Florence, Italy; LENS European Laboratory for Nonlinear Spectroscopy, Firenze, Italy

John F Federici

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

AM Finkel'stein

Department of Condensed Matter Physics, The Weizmann Institute of Science, Rehovot, Israel; Department of Physics and Astronomy, Texas A&M University, College Station, TX, United States

Paola Gallo

Dipartimento di Matematica e Fisica, Università "Roma Tre", Roma, Italy

Jorge M García

Instituto de Micro y Nanotecnología, IMN-CNM, CSIC, (CEI UAM+CSIC), Isaac Newton, Madrid, Spain

Ian Gatley

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

Samuel Gatley

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

Elena Gnani

Department of Electrical Electronic and Information Engineering (DEI), and Advanced Research Center on Electronic Systems E. de Castro (ARCES), University of Bologna, Bologna, Italy

M Goerdeler

Institut für Metallkunde und Metallphysik, Aachen, Germany

H Julian Goldsmid

School of Physics, University of New South Wales, Sydney, NSW, Australia

G Gottstein

Institut für Metallkunde und Metallphysik, Aachen, Germany

M Grundmann

Universität Leipzig, Leipzig, Germany

Sébastien Guenneau

The Blackett Laboratory, Department of Physics, Imperial College, London, United Kingdom

Ralf Hielscher

Fakultät für Mathematik, Technische Universität Chemnitz, Chemnitz, Germany

Y Hirayama

NTT Basic Research Laboratories, Kanagawa, Japan

Massimo Inguscio

LENS European Laboratory for Nonlinear Spectroscopy, Firenze, Italy; Campus Bio-Medico University of Rome, Rome, Italy

Hajime Ishihara

Department of Materials Engineering Science, Osaka University, Osaka, Japan; Center for Quantum Information and Quantum Biology, Osaka University, Osaka, Japan

EL Ivchenko

Ioffe Institute, Russian Academy of Sciences, St. Petersburg, Russia

Yoshihiro Iwasa

Department of Applied Physics and Quantum-Phase Electronics Center, The University of Tokyo, Tokyo, Japan; RIKEN Center for Emergent Matter Science, Wako, Japan

Wataru Izumida

Tohoku University, Sendai, Japan

Alexey Kavokin

International Center for Polaritonics, School of Science, Westlake University, Hangzhou, Zhejiang Province, China; Russian Quantum Center, Skolkovo, Moscow Region, Russia; Moscow Institute of Physics and

Technology, Institutskiy Pereulok, Dolgoprudny, Moscow Oblast, Russia

AV Kimmel

Institute for Molecules and Materials, Radboud University, Nijmegen, The Netherlands

Albert Kirakosyan

Department of Solid State Physics, Yerevan State University, Yerevan, Armenia

D Klenam

Academic Development Unit & School of Chemical and Metallurgical Engineering, University of the Witwatersrand, Johannesburg, South Africa

Alexander M Korsunsky

Trinity College, Oxford, United Kingdom

EE Krasovskii

Donostia International Physics Center DIPC, P. Manuel de Lardizabal 4, San Sebastián, Spain; Departamento de Polímeros y Materiales Avanzados: Física, Química y Tecnología, Universidad del País Vasco/Euskal Herriko Unibertsitatea, Donostia-San Sebastián, Spain; IKERBASQUE, Basque Foundation for Science, Bilbao, Spain

Wolfgang Lang

Faculty of Physics, University of Vienna, Vienna, Austria

Fabrice P Laussy

Faculty of Science and Engineering, University of Wolverhampton, Wolverhampton, United Kingdom; Russian Quantum Center, Skolkovo, Moscow Region, Russia

Jean-Pierre Leburton

University of Illinois at Urbana-Champaign, Urbana, IL, United States

AP Levanyuk

Department of Physics, University of Washington, Seattle, WA, United States

A-M Leventi-Peetz

Federal Office for Information Security (BSI), Bonn, Germany

R Livi

Dipartimento di Fisica e Astronomia, Università di Firenze and Sezione INFN di Firenze, Sesto Fiorentino, Italy; ISC-CNR, Sesto Fiorentino, Italy

AC Lund

Massachusetts Institute of Technology, Cambridge, MA, USA

Wenchen Luo

School of Physics and Electronics & Hunan Key Laboratory of Nanophotonics and Devices, Central South University, Changsha, China

LB Ma

Institute for Integrative Nanosciences, Leibniz IFW Dresden, Dresden, Germany

J Maier

Physical Chemistry of Solids, Max Planck Institute for Solid State Research, Stuttgart, Germany

Aram Manaselyan

Department of Solid State Physics, Yerevan State University, Yerevan, Armenia

Euclydes Marega Jr

Instituto de Física de São Carlos, Universidade de São Paulo, São Carlos, SP, Brazil

G Mattei

CNR, Istituto dei Sistemi Complessi, Rome, Italy

JD Maynard

The Pennsylvania State University, University Park, PA, United States

F McBagonluri

Department of Mechanical Engineering, Academic City University College, Accra, Ghana

Mariana Medina-Sánchez

Micro- and NanoBiomedical Engineering Group (MNBE), Institute for Integrative Nanosciences, Leibniz Institute for Solid State and Materials Research (IFW), Dresden, Germany; Chair of Micro- and NanoSystems, Center for Molecular Bioengineering (B CUBE), Dresden University of Technology, Dresden, Germany

Vram Mughnetsyan

Department of Solid State Physics, Yerevan State University, Yerevan, Armenia

Yuli V Nazarov

Department of Quantum Nanoscience, Kavli Institute of Nanoscience, Delft University of Technology, The Netherlands

David Neilson

CMT Group, Department of Physics, University of Antwerp, Antwerp, Belgium; ARC Centre of Excellence for Future Low Energy Electronics Technologies, School of Physics, The University of New South Wales, Sydney, NSW, Australia

Jessy Nemati

Department of Physics, New Jersey Institute of Technology, Newark, NJ, United States

Yoji Ohashi

Department of Physics, Keio University, Yokohama, Japan

Michael O'Donovan

Photonics Theory Group, Tyndall National Institute, Cork, Ireland; School of Physics, University College Cork, Cork, Ireland

Eoin P O'Reilly

Photonics Theory Group, Tyndall National Institute, Cork, Ireland; School of Physics, University College Cork, Cork, Ireland

J M Parker

Department of Materials Science and Engineering, Sheffield University, Sheffield, United Kingdom

G Pastore

Dipartimento di Fisica, Università di Trieste, Trieste, Italy

Shenglin Peng

School of Information Science and Technology, Northwest University, Xi'an, China

Luís Fernando C Pereira

Department of Physics, Federal University of Maranhão, São Luís, Maranhão, Brazil

Jan Petzelt

Institute of Physics, Czech Academy of Sciences, Prague, Czech Republic

GVSS Prasad

Institut für Metallkunde und Metallphysik, Aachen, Germany

Nick P Proukakis

Joint Quantum Centre (JQC) Durham–Newcastle, School of Mathematics, Statistics and Physics, Newcastle University, Newcastle upon Tyne, United Kingdom

Alessio Recati

Pitaevskii BEC Center, CNR-INO and Department of Physics, University of Trento, Trento, Italy

Gregory S Rohrer

Department of Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States

Rudolf A Römer

Department of Physics, University of Warwick, Coventry, West Midlands, United Kingdom

Mauro Rovere

Dipartimento di Matematica e Fisica, Università "Roma Tre", Roma, Italy

Ivan Rychetský

Institute of Physics, Czech Academy of Sciences, Prague, Czech Republic

W Schattke

Donostia International Physics Center DIPC, P. Manuel de Lardizabal 4, San Sebastián, Spain; Institut für Theoretische Physik und Astrophysik der Christian-Albrechts-Universität, Leibnizstraße 15, Kiel, Germany

CA Schuh

Massachusetts Institute of Technology, Cambridge, MA, USA

Stefan Schulz

Photonics Theory Group, Tyndall National Institute, Cork, Ireland; School of Physics, University College Cork, Cork, Ireland

G Schwiete

Department of Physics and Astronomy, The University of Alabama, Tuscaloosa, AL, United States

Armen Sedrakian

Frankfurt Institute for Advanced Studies, Frankfurt am Main, Germany; Institute of Theoretical Physics, University of Wrocław, Wrocław, Poland

F Seitz

Rockefeller University, New York, NY, USA

V Silkin

Donostia International Physics Center DIPC, P. Manuel de Lardizabal 4, San Sebastián, Spain; Departamento de Polímeros y Materiales Avanzados: Física, Química y Tecnología, Universidad del País Vasco/Euskal Herriko Unibertsitatea, Donostia-San Sebastián, Spain; IKERBASQUE, Basque Foundation for Science, Bilbao, Spain

Edilberto O Silva

Department of Physics, Federal University of Maranhão, São Luís, Maranhão, Brazil

Robert P Smith

Clarendon Laboratory, University of Oxford, Oxford, United Kingdom

W Soboyejo

Department of Mechanical Engineering, Worcester Polytechnic Institute, Worcester, MA, United States

EB Sonin

Racah Institute of Physics, Hebrew University of Jerusalem, Jerusalem, Israel

Sandro Stringari

Pitaevskii BEC Center, CNR-INO and Department of Physics, University of Trento, Trento, Italy

BA Strukov

Department of Physics, Lomonosov Moscow State University, Moscow, Russia

T Takahashi

University of Tokyo, Tokyo, Japan

Yoshiro Takahashi

Department of Physics, Graduate School of Science, Kyoto University, Kyoto City, Japan

EV Thuneberg

QTF Centre of Excellence, Department of Applied Physics, Aalto University, Espoo, Finland

V Yu Timoshenko

*Faculty of Physics, Lomonosov Moscow State University,
Moscow, Russia*

MP Tosi

Scuola Normale Superiore, Pisa, Italy

V Unikandanunni

*Department of Physics, Stockholm University, Stockholm,
Sweden*

M Van Rossum

IMEC, Leuven, Belgium

JW Wang

*School of Electronic and Information Engineering, Harbin
Institute of Technology (Shenzhen), Shenzhen, China*

Nickolas Warholak

*Department of Physics, New Jersey Institute of Technology,
Newark, NJ, United States*

Stuart I Wright

Kosuke Yoshioka

*Photon Science Center, School of Engineering, The
University of Tokyo, Tokyo, Japan*

CONTENTS OF VOLUME 3

Superfluidity <i>EV Thuneberg</i>	1
BEC-BCS crossover in ultracold atomic gases and neutron stars <i>Yoji Ohashi</i>	10
Superconductivity and superfluidity in neutron stars <i>Armen Sedrakian and John W Clark</i>	22
BEC-BCS crossover, condensed matter experiments <i>Kyosuke Adachi and Yoshihiro Iwasa</i>	31
Excitonic superfluidity in electron-hole bilayer systems <i>David Neilson</i>	38
Spin superfluidity <i>EB Sonin</i>	51
Bose–Einstein condensation <i>Leonardo Fallani, Massimo Inguscio, Alessio Recati, and Sandro Stringari</i>	68
Universality of Bose–Einstein condensation and quenched formation dynamics <i>Nick P Proukakis</i>	84
Interacting Bose-condensed gases <i>Christoph Eigen and Robert P Smith</i>	124
Cold-atom systems as condensed matter physics emulation <i>Yoshiro Takahashi</i>	135
Ionic and mixed conductivity in condensed phases <i>J Maier</i>	145
Electronic structure of liquids <i>G Pastore and MP Tosi</i>	161
Supercooled liquids <i>Paola Gallo and Mauro Rovere</i>	171
Glasses <i>J M Parker</i>	181
Disordered solids and glasses, electronic structure of <i>SR Elliott</i>	191
Acoustics: Physical principles and applications to condensed matter physics <i>JD Maynard</i>	200
Numerical methods for localization <i>Rudolf A Römer</i>	212
Disordered electron liquid with interactions: Theoretical aspects <i>AM Finkel'stein and G Schwiete</i>	220

Basics of simulations and carrier localization effects in semiconductor materials <i>Eoin P O'Reilly, Michael O'Donovan, and Stefan Schulz</i>	236
Conductivity, electrical <i>J Bass</i>	251
Coulomb blockade <i>Yuli V Nazarov</i>	260
Conductivity, thermal <i>K Behnia</i>	273
Transport properties: Mass transport <i>R Livi</i>	278
Ferroelectricity <i>AP Levanyuk, BA Strukov, and A Cano</i>	284
Planar quantum dots: Theoretical approaches <i>Aram Manaselyan, Vram Mughnetsyan, and Albert Kirakosyan</i>	297
Quantum dots: Optical properties <i>V Yu Timoshenko</i>	308
The physics of quantum dots <i>Jean-Pierre Leburton</i>	325
Self-organized semiconductor nanostructures (quantum dots, quantum rings and their arrays) <i>Euclides Marega Jr</i>	337
Optical properties in rolled-up structures <i>JW Wang and LB Ma</i>	354
Nanostructured superconductors <i>Wolfgang Lang</i>	368
Kondo effects in quantum dots: Theory <i>Wataru Izumida</i>	381

Abstract

This chapter gives an introduction to basic properties of superfluids. After defining the subject, we list systems where it occurs: liquid ^4He , liquid ^3He , dilute atomic gases, neutron stars and superconducting metals. The microscopic basis for the formation of the superfluid phase is considered in boson and fermion systems. The two-fluid model is introduced and some consequences are discussed. The quantization of circulation is presented. Quantized vortex lines are introduced and they are used to explain the structure of a rotating superfluid. Phase slip, Josephson effect and critical velocity are discussed.

Key points

- Definition of superfluidity
- Occurrence of superfluidity
- Microscopic basis of superfluidity
- Two-fluid model
- Quantized circulation, vortices and rotating superfluid
- Phase slip, Josephson effect and critical velocity

Introduction

Fluids (gases and liquids) are distinguished from solids by the property that they can flow. In almost all cases there is viscosity associated with the flow. Due to viscosity, the flow energy is gradually dissipated into heat. Contrary to this common situation, there is a special class of fluids, which can flow without viscosity. These are called superfluids and the phenomenon is called superfluidity (London, 1954; Tilley and Tilley, 1990; Guénault, 2003; Annett, 2004; Leggett, 2006; Bennemann and Ketterson, 2013; Barenghi and Parker, 2016). As a concrete example, consider a ring-shaped container filled with superfluid, see Fig. 1. Once the fluid is put into circular motion, it will continue to circulate and no energy is dissipated. The flow can continue as long as the external conditions remain unchanged, in particular the temperature is kept low enough.

Superfluids show many spectacular phenomena, which are discussed in Sections “Hydrodynamics,” “Quantization of circulation,” “Rotating superfluid and vortex lines,” “Phase slip, Josephson effect and critical velocity.” Before going into these we discuss the systems where superfluidity occurs (Section Occurrence) and the microscopic basis of superfluidity (Section Microscopic origin). While Section Microscopic origin gives deeper insight, it is not absolutely necessary for discussing the phenomena in Sections “Hydrodynamics,” “Quantization of circulation,” “Rotating superfluid and vortex lines,” “Phase slip, Josephson effect and critical velocity.”

Occurrence

Superfluidity occurs only in certain substances under special conditions. Superfluidity occurs at temperatures T below a transition temperature T_c , which strongly depends on the substance.

Fig. 1 Once generated, the circulation of a superfluid (with velocity v_s) persists as long as the experiment can be continued.

Fig. 2 Phase diagram of ^4He at low temperatures. ^4He remains liquid at zero temperature if the pressure is below 2.5 MPa (approximately 25 atm). The liquid has a phase transition to a superfluid phase, also known as He-II, at the temperature of 2.17 K (at vapor pressure).

Fig. 3 The phase diagram of ^3He at low temperatures. Note that the temperature is in units of millikelvin, in contrast to Fig. 2. Two superfluid phases, A and B, are shown. The figure is based on data by Greywall (1986).

As a first case we discuss liquid helium. Under standard pressure and temperature helium is a gas. It liquefies at temperatures around 4 K. Cooling further down, it enters the *superfluid phase* at temperatures around 2 K, depending on pressure (Wilks, 1967). The phase diagram of natural helium at low temperatures is shown in Fig. 2. Natural helium consists essentially of isotope ^4He . A ^4He atom is a *boson* since both the electronic spin and the nuclear spin vanish. Helium was first liquefied in 1908 and the superfluid phase was discovered in 1938.

Helium has another stable isotope, ^3He . A ^3He atom is a *fermion* because the nuclear spin is $1/2$. At temperatures below a few kelvin, its behavior is radically different from the isotope ^4He . It also becomes superfluid, but at temperatures that are a factor of one thousand smaller than for ^4He (Wheatley, 1975; Leggett, 1975; Vollhardt and Wölfle, 1990; Dobbs, 2001). The phase diagram of ^3He at low temperatures is shown in Fig. 3. ^3He has three different superfluid phases, A, A1, and B. The A1 phase only appears in magnetic field, and therefore is not visible in Fig. 3. Recently, also the polar phase has been demonstrated by adding dilute impurity, aerogel, into the liquid (Dmitriev et al., 2015). The superfluid phases A and B of ^3He were found in 1972.

With laser cooling it is possible to cool certain dilute atomic gases like ^1H , ^6Li , ^7Li , ^{23}Na , ^{40}K , ^{87}Rb to very low temperatures. These gases condense to superfluid state at temperatures on the order of 1 μK , depending on the density and on atomic interactions (Pethick and Smith, 2002; Pitaevskii and Stringari, 2003; Leggett, 2006; Bloch et al., 2008). This state shows many properties that are similar to the helium superfluids, although it is not a thermodynamically stable state, and therefore the flow cannot last for ever. Most of the discussion in this article applies also to condensed gases. An important difference is that instead of container walls for helium liquids, one has to consider the confining potential of the gas, which can be generated either magnetically (by field

gradients) or optically (by laser beams). The gas atoms ^1H , ^7Li , ^{23}Na , ^{87}Rb are bosons while ^6Li and ^{40}K are fermions. Superfluid condensation in a gas was first found in ^{87}Rb in 1995.

Superfluidity is expected to occur also in astrophysical objects. The neutron liquid in a neutron star is believed to be in a superfluid state (Page et al., 2014; Gezerlis et al., 2014; Chamel, 2017). Also protons in a neutron star are expected to condense to a superfluid state. Both neutrons and protons are fermions. The superfluidity has been suggested as an explanation for the observed sudden changes in the rotation velocity of pulsars.

Superfluidity is closely related to *superconductivity* (Tinkham, 1996; Bennemann and Ketterson, 2008). Superconductivity means that electric current can flow without resistance. This phenomenon appears in several elemental metals like Al, Sn, and Nb at temperatures on the order of 10 K or below. It also appears in several alloys and compounds. Superconductivity arises from resistanceless motion of the conduction electrons in a metal. Therefore, superconductivity can be understood as Superfluidity of the conduction electrons, which are fermions. Part of the discussion in this article applies also to superconductivity, but there are differences caused mainly by two reasons. (a) Electrons have electric charge and therefore their motion is essentially coupled with magnetic field. (b) The crystal lattice of the ions constitutes a preferred frame of reference, which does not exist for helium liquids. Superconductivity was first found in Mercury in 1911.

Microscopic origin

In short, superfluidity can be explained as a quantum mechanical effect that shows up on a macroscopic scale.

Quantum mechanics is crucial in understanding the microscopic world. It explains that electrons in atoms have only discrete energies. There is no friction on the atomic scale, and the electrons can circulate the nucleus without losing energy.

We know that quantum mechanics rarely shows up on macroscopic scale. Instead of quantum mechanics, macroscopic objects obey the rules of classical physics. The reason is that a macroscopic sample consists of large number of particles and, instead of individual particles, one can only observe their average behavior. Usually the particles are in different quantum states, and an average over them obeys classical laws of physics. Examples of these laws are the Navier-Stokes equations for fluids and Ohm's law for electrical conduction.

Superfluidity is an exception to this general rule. In superfluids a macroscopic number of particles is in the same quantum state. It follows that summing over particles does not lead to averaging, but produces a *macroscopic wave function*.

Consider a free particle with mass m and momentum p . Its kinetic energy is $E = p^2/2m$. Its state is represented by the single-particle wave function

$$\psi(\mathbf{r}) = \frac{1}{\sqrt{V}} \exp\left(\frac{i}{\hbar} \mathbf{p} \cdot \mathbf{r}\right), \quad (1)$$

where V is the volume of the system and $\hbar = 2\pi\hbar$ the Planck constant. Below we also use the wave vector $\mathbf{k}$ so that $\mathbf{p} = \hbar\mathbf{k}$. The wave function of a many body system $\Psi(\mathbf{r}_1, \mathbf{r}_2, \dots)$ is more general and depends on the coordinates $\mathbf{r}_i$ of all particles, $i = 1, 2, \dots, N$, where N is the number of particles.

Further analysis depends essentially whether the particles are bosons or fermions. We now assume the particles are bosons. This means that the total wave function must be symmetric when exchanging any pair of particles. In the case of two particles this means $\Psi(\mathbf{r}_1, \mathbf{r}_2) = \Psi(\mathbf{r}_2, \mathbf{r}_1)$. Further we assume that there is no interaction between the bosons. It can be shown that the occupation of the lowest energy state becomes macroscopic, if the temperature T is less than

$$T_{BE} = \frac{\hbar^2}{2\pi m k_B} \left(\frac{N}{2.612V}\right)^{2/3} \quad (2)$$

Here k_B the Boltzmann constant. This is known as *Bose-Einstein condensation* (BEC). The wave function (1) of the lowest energy state ($p = 0$) becomes macroscopic. At zero temperature, all particles are in this state. While the ideal gas model explains Bose-Einstein condensation, it is quite insufficient in other respects. The interactions between particles are essential for the system to show superfluidity (see Section "Phase slip, Josephson effect and critical velocity"). In interacting system the macroscopically occupied state $\psi(\mathbf{r})$ need not be the lowest energy state, and thus the macroscopic wave function can be nontrivial. In Bose gases (^{87}Rb , etc.) the interactions are weak, and a quantitative description can be achieved by the relatively simple Gross-Pitaevskii equation. In liquid ^4He the interactions are much stronger, and a quantitative theory is not easily achieved. But even in that case, formula (2) gives 3.1 K, which is not too far from the measured value. A simple phenomenological description of ^4He superfluid is obtained by considering its elementary excitations, see Fig. 4A. The excitation spectrum is linear, $E(p) = cp$ at small momenta, where c is the velocity of sound. These excitations are known as phonons. At larger momenta $E(p)$ starts to decrease and it attains a minimum. The excitations near this minimum are known as rotons. In Bose gases only phonon excitations are visible because of weaker interactions.

Let us now turn to fermions. The fermions have spin, which has to be described by an additional index σ . Here we consider only spin-half particles, where the spin projection σ takes two values, $\sigma = \pm \frac{1}{2}$. The wave function of a fermion system is $\Psi(\mathbf{r}_1, \sigma_1, \mathbf{r}_2, \sigma_2, \dots)$, and it has to be antisymmetric in the exchange of any pair of particles. For a two-particle state this means

Fig. 4 The energy of elementary excitations as a function of the wave number, $E(k)$. (A) Elementary excitations in liquid ^4He at vapor pressure (black solid line). The free atom kinetic energy is given by dashed line. The figure is based on neutron-scattering data by Henshaw and Woods (1961). (B) Sketch of elementary excitations of a degenerate fermion system. The excitation energy in the normal state (dashed lines) vanishes at the Fermi surface, $k = k_F$. The excitations are particle type at $k > k_F$ and hole type at $k < k_F$. In the superfluid state (black solid line) an energy gap Δ opens up. For visibility of the figure, the scales are far from those ones in superconducting metals and liquid ^3He . In both panels the sloped straight lines (red) correspond the critical velocity according to Landau criterion (17).

$$\Psi(\mathbf{r}_1, \sigma_1, \mathbf{r}_2, \sigma_2) = -\Psi(\mathbf{r}_2, \sigma_2, \mathbf{r}_1, \sigma_1). \quad (3)$$

This implies that the occupation of any single-particle state only can be zero or one. This is known as the *Pauli exclusion principle*. Thus macroscopic occupation of a single-particle state (1) is not possible.

Superfluidity in a fermion system can appear as a result of an attractive interaction between particles. Such an interaction can cause formation of pairs. Each pair has to satisfy the antisymmetry condition (3). However, a pair is a unit that behaves like a boson. In particular, it is not excluded that several pairs are in the same pair state. Superfluidity in fermion systems can be understood as a macroscopic occupation of a single pair state. Thus superfluidity can be understood as Bose condensation of pairs.

The spin part of the pair wave function has four different possibilities. These can be classified as a singlet state

$$\uparrow\downarrow - \downarrow\uparrow \quad (4)$$

(which is a compact notation for $\delta_{\sigma_1, 1/2} \delta_{\sigma_2, -1/2} - \delta_{\sigma_1, -1/2} \delta_{\sigma_2, 1/2}$) and three triplet states, which can be chosen as

$$-\uparrow\uparrow + \downarrow\downarrow, i(\uparrow\uparrow + \downarrow\downarrow), \uparrow\downarrow + \downarrow\uparrow. \quad (5)$$

Let us first study the case of spin singlet (4). The pair wave function in this case is assumed to be of the form

$$\Psi(\mathbf{r}_1, \sigma_1, \mathbf{r}_2, \sigma_2) = \psi\left(\frac{\mathbf{r}_1 + \mathbf{r}_2}{2}\right) \chi(\mathbf{r}_1 - \mathbf{r}_2)(\uparrow\downarrow - \downarrow\uparrow) \quad (6)$$

where we have separated the orbital wave function to a center of mass part ψ and a relative part χ . The singlet spin state (4) is antisymmetric in the exchange of the two spins. In order to satisfy pair antisymmetry (3), the corresponding orbital part $\chi(\mathbf{r}_1 - \mathbf{r}_2)$ has to be symmetric, $\chi(\mathbf{r}) = \chi(-\mathbf{r})$. In most superconductors the pair wave function is of the form (6). In majority of them (Al, Sn, Nb, ...) χ is approximately independent of the direction of $\mathbf{r}_1 - \mathbf{r}_2$. This is called s-wave pairing in analogy with s, p, d, etc., atomic orbitals. In high- T_c superconductors there is strong evidence of d-wave symmetry of χ . In Fermi gases s-wave pairing has been observed with the spin being pseudo spin formed by two atomic hyperfine states (Zwierlein, 2014).

Another alternative is that the spin state of a pair is triplet (5). This case is realized in ^3He and possibly in some superconductors. In ^3He the orbital wave function is of p type. There are three degenerate p-wave states p_x , p_y and p_z . The pair wave function can be written as

$$\Psi(\mathbf{r}_1, \sigma_1, \mathbf{r}_2, \sigma_2) = \sum_{j=1}^3 \sum_{\mu=1}^3 \psi_{\mu j}\left(\frac{\mathbf{r}_1 + \mathbf{r}_2}{2}\right) p_j(\mathbf{r}_1 - \mathbf{r}_2) i\hat{\sigma}_\mu \hat{\sigma}_2. \quad (7)$$

Here $i\hat{\sigma}_\mu \hat{\sigma}_2$ denotes the same three spin states as in Eq. (5), but expressed using Pauli spin matrices $\hat{\sigma}_i$.

The macroscopic wave function of bosons is called *order parameter*, since it describes ordering of the particles and it vanishes in the normal fluid phase. For fermions the same role is played by the center of mass part of the pair function. This is the soft degree of freedom, which can change as a function of time and location, whereas the other parts in the pair wave function (6)–(7) are fixed. We see that the order parameter in ^4He and in most superconductors is a complex-valued scalar ψ , but in ^3He it is a 3×3 matrix $\psi_{\mu j}$. The order parameter in condensed boson gases is a scalar in the simplest case, but including atoms in different hyperfine states allows more complicated forms. In neutron stars both spin singlet and triplet pairing has been predicted to occur.

An important energy scale in a Fermi system is *Fermi energy*. It is the energy up to which all noninteracting single particle states would be filled at zero temperature. It is $E_F = p_F^2/2m$, where the Fermi momentum p_F is related to the particle density by

$N/V = p_F^3/3\pi^2\hbar^3$. Compared with thermal energy $k_B T$, it corresponds to Fermi temperature $T_F = E_F / k_B$. For ^3He $T_F \sim 1$ K and for elemental superconductors $T_F \sim 10^4$ K. We see that for both ^3He and superconductors, the transition temperature is small compared to the Fermi temperature, $T_c / T_F \sim 10^{-3}$ or less. This implies that only excitations that have low energy ($\ll E_F$) close to the Fermi surface $p = p_F$ play role in Superfluidity. Such excitations are described by Landau's *Fermi liquid theory*. The normal state excitations are quasiparticles which are free-particle like and weakly interacting, see Fig. 4B. In the superfluid state pairs are formed. They are weakly bound and called Cooper pairs. The pair condensation opens an energy gap in the excitation spectrum. Quantitative theory of fermion superfluids is based on the Bardeen-Cooper-Schrieffer (BCS) theory of superconductivity (Bardeen et al., 1957). The extension to cover superfluid ^3He is discussed by Serene and Rainer (1983).

Above we have discussed the boson and fermion cases separately. But in fact, one can think to go continuously from one case to the other. By increasing the attractive interaction of the fermions in a Cooper pair, one could transform it to a strongly bound pair, which could be considered as a single Bose particle. This BCS-BEC crossover has been experimentally studied in fermion gases.

Hydrodynamics

Many properties of superfluids can be understood in terms of the *two-fluid* model. The basic assumption is that the liquid consists of two parts. These are called the *superfluid* and *normal components*. The current density $\mathbf{j}$ can be represented as a sum

$$\mathbf{j} = \rho_s \mathbf{v}_s + \rho_n \mathbf{v}_n. \quad (8)$$

Here ρ_s and $\mathbf{v}_s$ are the density and velocity of the superfluid component and ρ_n and $\mathbf{v}_n$ are the corresponding quantities for the normal component. The liquid density is the sum of the two densities, $\rho = \rho_s + \rho_n$. The superfluid component can flow without viscosity and it carries no heat or entropy. Moreover it is curl free,

$$\nabla \times \mathbf{v}_s = 0. \quad (9)$$

(This is valid only in uncharged superfluids.) The normal component behaves more like a usual viscous fluid.

The two-fluid model can be justified from the microscopic theory discussed in Section [Microscopic origin](#). The superfluid component corresponds to particles in the macroscopic wave function, and the normal component to particles in the excited states. The densities of the two components depend on temperature. At zero temperature all particles are in the condensate, $\rho_n = 0$ and $\rho_s = \rho$. With increasing temperature more particles are excited out of the condensate to the excited states. Thus $\rho_n(T)$ grows and $\rho_s(T)$ drops, see Fig. 5. The superfluid transition T_c is the temperature at which the condensate ceases to exist, and corresponds to $\rho_s = 0$ and $\rho_n = \rho$.

In application of the two-fluid model we can distinguish two cases. Consider first the case that only the superfluid component moves, $\mathbf{v}_n = 0$. This can be realized in the ring-shaped container (Fig. 1). Once the superfluid component is set into motion, it can

Fig. 5 The normal fluid fraction ρ_n/ρ as a function of temperature relative to T_c . The lowest curve is for superfluid ^4He at vapor pressure and is based on data in Peshkov (1946). The other curves are for superfluid ^3He -B at melting pressure (upper curve) and vapor pressure (middle curve) according to weak coupling theory (BCS theory generalized to triplet p -pairing and including Fermi-liquid interactions). The superfluid fraction $\rho_s/\rho = 1 - \rho_n/\rho$.

Fig. 6 A difference in temperature ΔT generates flow of normal and superfluid components in opposite directions, and a pressure difference Δp appears. The viscosity of the normal component causes v_n to vanish at walls. The superfluid velocity $v_s(z)$ has to be constant in order to be curl free (9). In a channel with closed ends the total mass flow J has to vanish.

persists because flow is ideal with no viscosity. This explains that superfluid can flow through narrow pores or as a thin film in response to small or vanishing pressure difference.

The other type of motion is that also the normal component participates in it. This takes place, for example, when an object moves in the liquid. Because of motion of the normal component, viscous forces and dissipation appear. This explains that nonvanishing viscosity is measured with a viscometer, where the superfluid is placed between two plates or coaxial cylinders that move at different velocities. The measured viscosity can still be small at low temperatures, where the normal component density is vanishingly small.

Superfluids show peculiar mixing of thermal and mechanical properties. Consider superfluid in a channel which is heated at one end, see Fig. 6. The superfluid component is attracted to the hot region because the chemical potential is lower there. As a consequence a pressure difference appears. This drives the normal component in the direction of decreasing temperature and convects the heat away from the source. Assuming the geometry does not allow net mass transfer, the mass transported by the normal and superfluid components in opposite directions are equal in magnitude. Such *counter flow* can lead to exceptionally large heat conductance.

In addition to usual sound wave, superfluids have another propagating mode. This *second sound* is an oscillation where normal and superfluid components move in opposite directions. This leads to oscillation of temperature whereas the density remains nearly constant. Second sound can be generated by heating the superfluid periodically, and standing waves of temperature have been demonstrated experimentally.

In addition to the mass current $\mathbf{j}$, there can be persistent spin currents. This is possible in superfluids whose order parameter is more complicated than scalar (^3He). Spin current is described by a tensor $j_{\mu j}^{\text{spin}}$. The index $\mu = x, y, z$ indicates the direction of spin angular momentum that is flowing, and $j = x, y, z$ indicates the direction of the flow. Even in equilibrium the order parameter of ^3He has nontrivial spatial variation called *texture*. This is associated with persistent spin currents and, in case of $^3\text{He-A}$, also with persistent mass currents.

Quantization of circulation

Consider a superfluid with order parameter ψ . (Assume an uncharged superfluid, ψ can be either scalar or matrix.) The superfluid velocity $\mathbf{v}_s$ can be expressed as a function of the order parameter as

$$\mathbf{v}_s = \frac{\hbar}{M} \nabla \phi. \quad (10)$$

Here $\phi(\mathbf{r})$ is the phase of the order parameter, $\psi(\mathbf{r}) = A e^{i\phi(\mathbf{r})}$, and the amplitude A is assumed constant. M is the boson mass, i.e., the mass of a particle in a boson superfluid and the mass of a pair in a fermion superfluid. Eq. (10) can be justified starting from the expression of current in quantum mechanics.

An alternative form of Eq. (10) is obtained by taking line integral along a closed path,

$$\oint \mathbf{v}_s \cdot d\mathbf{l} = N \frac{\hbar}{M}. \quad (11)$$

Here we have used the property that ϕ is defined modulo 2π , and N is an integer. Eq. (11) is known as *quantization of circulation*. The curl-free condition (9) is a direct consequence of Eq. (10) or (11).

Consider again superfluid in a ring-shaped container (Fig. 1). We can apply Eq. (11) to a path in the ring. We see that, in addition to being persistent, the superfluid velocity can only have discrete values. A similar phenomenon in superconductors is *flux quantization*. It says that magnetic flux through a ring shaped superconductor is an integral multiple of flux quantum $\Phi_0 = h/2e$, where e is the elementary charge.

Fig. 7 (A) Schema of a vortex line, where the phase of the order parameter changes by 2π when encircling the line. (B) Dependence of the azimuthal velocity field (12) on the distance r from the vortex line.

Fig. 8 In a rotating container the vortex lines form a regular array so that the superfluid and normal fluid velocities, v_s and v_n are equal on the average. In equilibrium the vortex array rotates rigidly with the container.

Rotating superfluid and vortex lines

Let us consider superfluid in a container that is rotated with angular velocity Ω . The normal component will follow this motion because of its viscosity. In equilibrium it rotates uniformly with the container, $v_n = \Omega \times r$. This is not possible for the superfluid component because it has to be curl free (9). [Eq. (9) should be compared to $\nabla \times v_n = 2\Omega$.]

The rotating state of a superfluid is most commonly realized by *vortex lines* (Andronikashvili and Mamaladze, 1966; Donnelly, 1991). On a path around the vortex line, the phase ϕ changes by 2π (or an integral multiple of it). This is illustrated in Fig. 7. Equivalently, the circulation of superfluid velocity (11) around the vortex line is h/M . Assuming cylindrical symmetry, the phase ϕ is the same as the azimuthal angle in the cylindrical coordinate system (r, ϕ, z) . The velocity field can be calculated from Eq. (10):

$$v_s = \frac{\hbar}{Mr} \hat{\phi}, \quad (12)$$

where $\hat{\phi}$ is a unit vector in the azimuthal direction.

The structure of the rotating state is determined by minimum of free energy. The rotation of the container is taken into account by minimizing $F = F_0 - L \cdot \Omega$, where F_0 is the free energy functional in the stationary case and L the angular momentum. In the two-fluid model this reduces to

$$F = \int d^3r \frac{1}{2} \rho_s (v_s - v_n)^2 + \text{constant}. \quad (13)$$

Thus the optimal solution corresponds to v_s as equal as possible to $v_n = \Omega \times r$, but subject to condition (10). This is achieved by a regular array of vortex lines, see Fig. 8. The number of vortex lines n per unit area is determined by the condition that the circulations of normal and superfluid velocities are the same over an area containing many vortex lines. This yields

$$n = \frac{2M\Omega}{h}. \quad (14)$$

There are approximately 1000 vortex lines in a circular container of radius 1 cm that is rotating 1 round per minute.

Vortex lines in an uncharged superfluid are analogous to *flux lines*, which occur in type II superconductors. Flux lines of superconductors appear in magnetic field, which is analogous to rotation of an uncharged superfluid.

The velocity field (12) of a vortex diverges at the vortex line. Thus there must be a *vortex core*, where the two-fluid description is insufficient. A finite energy in the vortex core is achieved if the amplitude of the order parameter vanishes at the vortex line. This is

the case for a scalar order parameter. For a matrix order parameter it is not necessary that all components of the matrix vanish at the line. Such vortex lines are realized in superfluid $^3\text{He-B}$.

The quantization of the superfluid velocity (11) is not always true for uncharged superfluids. This happens when there is an additional contribution to the superfluid velocity (10) coming from the matrix form of the order parameter. Such a case is realized in superfluid $^3\text{He-A}$, and careful reanalysis of the rotating state is needed. It turns out that, in addition to one-dimensional vortex lines, the vorticity may be arranged as two-dimensional vortex sheets and three-dimensional textures. All these have been confirmed experimentally (Lounasmaa and Thuneberg, 1999). In any case, a homogeneous rotation of the superfluid is excluded. Many more topological objects in quantum liquids and their parallels in particle physics and cosmology are discussed by Volovik (2003).

Besides rotating superfluid, vortex lines appear also in other circumstances. Vortices are important in limiting the maximal flow velocity, as will be discussed in the following section. By strong mechanical driving or by large thermal counterflow (Fig. 6) one can generate a large number of vortices. This is the quantum version of turbulence (Skrbek et al., 2021). In three dimensions the energy of vortex lines is high relative to the quasiparticle excitations, and therefore they are not important for thermodynamics. This changes in a thin liquid film, which forms essentially a two-dimensional system. The transition from superfluid to normal state can be seen as formation of free vortices that destroy the superfluid coherence, which is known as Kosterlitz-Thouless transition.

Phase slip, Josephson effect and critical velocity

Let us study superflow in a channel under thermal equilibrium ($v_n = 0$). The maximum supercurrent is determined by a process called *phase slip*. Consider that a short piece of vortex line is nucleated at a surface on one side of the channel. This vortex expands, goes through the whole cross section of the channel, and finally disappears on the other side. As a result of this process, the phase difference $\Delta\phi$ between the ends of the channel has changed by 2π . Part of the superfluid kinetic energy is dissipated in the motion of the vortex. This means that the flow ceases to be dissipationless above a critical velocity for phase slips. Phase slips preferentially take place in constrictions of the flow channel, where the superfluid velocity has its maximum value.

A special type of phase slip takes place in very short constrictions, where Eq. (10) ceases to be valid. An ideally short constriction shows the *Josephson effect*, where the supercurrent J_s depends on the phase difference $\Delta\phi$ as

$$J_s = J_c \sin(\Delta\phi), \quad (15)$$

and J_c is a constant. Moreover, the time derivative of $\Delta\phi$ is proportional to the difference of the chemical potential $\Delta\mu$ on the two sides of the constriction,

$$\frac{d\Delta\phi}{dt} = -\frac{2\Delta\mu}{\hbar}. \quad (16)$$

Combining the two equations, one sees that a constant $\Delta\mu$ generates an oscillating current at the frequency $2\Delta\mu/\hbar$.

The Josephson effect takes place in all superfluids. It has extensively been studied in superconductors, where it is straightforward to fabricate barriers through which electrons can tunnel. For helium one has to use sufficiently small constrictions. Josephson effect in ^3He has been discussed by Davis and Packard (2002).

Let us consider a macroscopic moving object in a stationary superfluid. As discussed above, there generally is viscous drag from the normal component, but restricting to low temperatures, say below $0.2T_\sigma$, the normal fraction is vanishingly small. In this case the motion is nearly dissipationless as long as the object does not generate new excitations. The creation of excitations is limited by energy and momentum conservation. A simple calculation shows that no excitations are generated below the velocity

$$v_c = \min \frac{E(p)}{p}, \quad (17)$$

which means the minimum of $E(p)/p$ over all excitations. In connection of superfluidity, the velocity (17) is known as Landau velocity. It is more general, however, because the condition $v < v_c = \min \omega(k)/k$ means relatively low dissipation in any system, where the medium has waves with angular frequency ω and wave number k . The critical velocity (17) can also be derived from the condition that the waves generated by the object are stationary in the frame where the object is at rest. This is familiar to us, for example, from waves generated by a ship on the surface of water.

When the object velocity exceeds the Landau velocity v_c , a steep increase of the drag force is expected. Let us examine this in special cases. For ^4He the critical velocity is determined by the roton minimum [sloped line in Fig. 4A]. This gives $v_c \approx 60$ m/s. Landau critical velocity has been observed for ions moving in superfluid ^4He under pressure. In most experiments, the measured critical velocity is much lower. This is commonly interpreted to be caused by vortices, which are hard to avoid in a macroscopic set up.

For $^3\text{He-B}$ the Landau velocity $v_c = \Delta/p_F$, which corresponds to 27 mm/s at vapor pressure. Again, critical velocity of this magnitude has been seen with moving ions. For macroscopic objects the measured critical velocity is smaller than this. However, a recent experiment observes very little dissipation up to velocity $\sim 2v_c$ (Bradley et al., 2016). At the time of writing, this is not understood theoretically (Kuorelahti et al., 2018).

Landau velocity has also been applied to cases where only the superfluid component is in motion. For example, in ideal boson gas and in normal state fermions (dashed lines in Fig. 4) it gives vanishing critical velocity, $v_c = 0$. This is consistent with other

arguments that these systems are not superfluids. However, for non-s-wave pairing of fermions, it is possible that the energy gap Δ depends on the point on the Fermi surface, and can have nodes, leading to $v_c = 0$. Such a case appears $^3\text{He-A}$. In this case the vanishing of the Landau velocity does not imply absence of superfluidity.

Conclusion

We have given introduction to the basic properties of superfluids. Several more advanced topics are mentioned, but all details of them are left to be read from the given references and other literature.

Abstract

This chapter reviews how the BCS-type Fermi superfluid discussed in superconductivity continuously changes to the Bose-Einstein condensation of tightly bound molecules, as the strength of a pairing interaction between fermions increases. Theoretical treatment and basic properties of this quantum many-body phenomenon are explained. Realization in ultracold ^{40}K and ^6Li Fermi gases with a Feshbach resonance, as well as a similar phenomenon predicted in the low-density crust regime of neutron stars, are also addressed.

Key points

- The BEC-BCS crossover provides a unified description of the Fermi and the Bose superfluids.
- This phenomenon has been realized in ^{40}K and ^6Li Fermi atomic gases, by using a tunable pairing interaction associated with a Feshbach resonance.
- A similar phenomenon is predicted in the low-density crust regime of a neutron star. In this system, the increase of the neutron number density as one goes inside the star effectively tunes the strength of a pairing interaction.
- The mean-field BCS theory can describe the BEC-BCS crossover at $T = 0$, when strong-coupling corrections to the Fermi chemical potential are taken into account.
- To evaluate T_c in the BEC-BCS crossover region, one needs to include pairing fluctuations, going beyond the mean-field BCS theory.

Introduction

The BEC (Bose-Einstein condensation)-BCS (Bardeen-Cooper-Schrieffer) crossover is a quantum many-body phenomenon, where the character of a Fermi superfluid continuously changes from the weak-coupling BCS-type (which is discussed in superconductivity) to the BEC of tightly bound molecules, as one increases the strength of a pairing interaction between fermions. Here, ‘crossover’ means the absence of any phase transition during the change from the BCS to BEC region. The BEC-BCS crossover was originally proposed in the field of superconductivity in 1960s (Eagles, 1969); however, since the experimental tuning of interaction strength was not easy, no one could realize this crossover phenomenon in the 20th century.

This situation drastically changed in 2004, when the superfluid phase transition was experimentally achieved in an ultracold ^{40}K Fermi atomic gas (Regal et al., 2004). Soon later, a superfluid ^6Li Fermi gas was also realized (Zwierlein et al., 2004; Kinast et al., 2004; Bartenstein et al., 2004). These Fermi atomic gases are experimentally prepared by trapping vaporized atoms in a harmonic potential produced by magnetic/optical manner, and then cooling the system down to below micro-Kelvin by using laser cooling, as well as evaporative cooling. While the pairing interaction in conventional s-wave superconductivity (such as Al) is mediated by phonon (Fig. 1(a)), superfluid ^{40}K and ^6Li Fermi gases use a pairing interaction associated with a Feshbach resonance (Chin et al., 2010) (Fig. 1(b)). This pairing mechanism has the unique property that one can tune the interaction strength by adjusting an external magnetic field. Indeed, by using this advantage, the superfluid phase transition and the BEC-BCS crossover were simultaneously realized in ^{40}K and ^6Li Fermi gases with a Feshbach resonance.

In the low-density crust regime of a neutron star, neutron liquid is considered to be in the s-wave superfluid state (Gandolfi et al., 2015) by an attractive interaction with the s-wave scattering length $a_s \simeq -18.5$ fm (Stoks et al., 1993). Using the typical value of the

Fig. 1 Illustration of pairing mechanism. (a) Phonon-mediated pairing interaction in superconductivity, working between spin- $\uparrow$ and spin- $\downarrow$ electrons. (b) Feshbach-induced tunable pairing interaction in ultracold Fermi atomic gases. Pseudospin- $\uparrow, \downarrow$ represent two atomic hyperfine states contributing to the Cooper-pair formation.

Fermi momentum $k_F \sim 1 \text{ fm}^{-1}$ in the neutron-star crust, the scaled interaction strength is estimated as $(k_F a_s)^{-1} \ll 1$, indicating that the system is close to the unitary limit ($(k_F a_s)^{-1} = 0$). Before 2004, any experiment could not access such a strong-coupling superfluid state, because all the conventional superconductors were in the weak-coupling BCS regime ($(k_F a_s)^{-1} \ll -1$). However, since the superfluid ^{40}K and ^6Li Fermi gases can widely cover various interaction strengths, ranging from $(k_F a_s) \lesssim -1$ to $(k_F a_s) \gtrsim +1$, we can now experimentally examine physical properties of a nearly unitary Fermi superfluid. In addition, although the value of the neutron s -wave scattering is fixed, the scaled interaction strength $(k_F a_s)^{-1}$ varies as one goes inside the neutron star, due to the increase of the neutron number density $\rho_N \propto k_F^3$. Thus, the tunable pairing interaction associated with a Feshbach resonance is also convenient to simulate this situation in terrestrial experiments.

In the followings, we overview the BEC-BCS crossover physics discussed in ^{40}K and ^6Li Fermi gases, as well as its application to the s -wave neutron superfluid predicted in the crust regime of a neutron star. For simplicity, we set $\hbar = k_B = 1$ and the system volume V is taken to be unity.

Overview of BEC-BCS crossover physics

CFB model and BCS model

A two-component ultracold Fermi gas with a Feshbach resonance is described by the following coupled fermion-boson (CFB) model Hamiltonian (Holland et al., 2001; Ohashi and Griffin, 2002):

$$\begin{aligned}
 H_{\text{CFB}} = & \sum_{\mathbf{p}, \sigma} \xi_{\mathbf{p}} c_{\mathbf{p}, \sigma}^\dagger c_{\mathbf{p}, \sigma} + \sum_{\mathbf{q}} \xi_{\mathbf{q}}^{\text{B}} b_{\mathbf{q}}^\dagger b_{\mathbf{q}} \\
 & + g \sum_{\mathbf{p}, \mathbf{q}} \left[b_{\mathbf{q}}^\dagger c_{-\mathbf{p}+\mathbf{q}/2, \downarrow} c_{\mathbf{p}+\mathbf{q}/2, \uparrow} + \text{h.c.} \right] \\
 & - U \sum_{\mathbf{p}, \mathbf{p}', \mathbf{q}} c_{\mathbf{p}'\mathbf{q}/2, \uparrow}^\dagger c_{-\mathbf{p}+\mathbf{q}/2, \downarrow}^\dagger c_{-\mathbf{p}'+\mathbf{q}/2, \downarrow} c_{\mathbf{p}'+\mathbf{q}/2, \uparrow}.
 \end{aligned} \tag{1}$$

Here, $c_{\mathbf{p}, \sigma}^\dagger$ is the creation operator of a Fermi atom with pseudospin $\sigma = \uparrow, \downarrow$, describing two atomic hyperfine states forming Cooper pairs. $\xi_{\mathbf{p}} = \epsilon_{\mathbf{p}} - \mu = \mathbf{p}^2/(2m) - \mu$ is the kinetic energy of a Fermi atom with an atomic mass m , measured from the Fermi chemical potential μ . $b_{\mathbf{q}}$ describes a molecular boson appearing in the intermediate state of a Feshbach resonance shown in Fig. 1(b). The molecular kinetic energy is given by

$$\xi_{\mathbf{q}}^{\text{B}} = \epsilon_{\mathbf{q}}^{\text{B}} - \mu_{\text{B}} = \frac{q^2}{2M} + 2\nu - \mu_{\text{B}}, \tag{2}$$

where 2ν is the threshold energy of a Feshbach resonance, and μ_{B} is the Bose chemical potential. Since one Feshbach molecule consists of two Fermi atoms, we take $M = 2m$ and $\mu_{\text{B}} = 2\mu$. The second line in Eq. (1) describes a Feshbach resonance with the coupling constant g , where two Fermi atoms form a quasi-molecular boson and it dissociates into two Fermi atoms again. $-U$ is a residual weak inter-atomic interaction which has nothing to do with the Feshbach resonance.

The CFB Hamiltonian in Eq. (1) makes us expect two kinds of superfluid states: One is characterized by the BEC order parameter, $\phi_{\text{m}} \equiv \langle b_{\mathbf{q}=0} \rangle$, and the other is characterized by the BCS superfluid order parameter,

$$\Delta \equiv U \sum_{\mathbf{p}} \langle c_{-\mathbf{p}, \downarrow} c_{\mathbf{p}, \uparrow} \rangle. \tag{3}$$

However, imposing the condition that the Bose order parameter ϕ_{m} has no time dependence in the thermal equilibrium state ($\partial \phi_{\text{m}} / \partial t = 0$), one exactly obtains the following relation (Ohashi and Griffin, 2003):

$$\phi_m = -\frac{g}{2\nu - 2\mu} \frac{\Delta}{U}. \quad (4)$$

Thus, only the superfluid phase with $\phi_m \neq 0$ and $\Delta \neq 0$ is actually possible.

Introducing the composite order parameter $\tilde{\Delta} \equiv \Delta - g\phi_m$, one finds that the mean-field gap equation to determine $\tilde{\Delta}$ has the form,

$$1 = \left[U_{\text{res}} + \frac{g^2}{2\nu - 2\mu} \right] \sum_p \frac{1}{2E_p} \tanh \frac{E_p}{2T}, \quad (5)$$

where

$$E_p = \sqrt{(\varepsilon_p - \mu)^2 + |\tilde{\Delta}|^2} \quad (6)$$

describes Bogoliubov single-particle excitations in the superfluid phase. From the comparison of Eq. (5) with the ordinary BCS gap equation (see Eq. (9)), we find that the Feshbach-induced pairing interaction ($\equiv U_{\text{FR}}$) is the second term in [...] in Eq. (5), that is,

$$U_{\text{FR}} = -\frac{g^2}{2\nu - 2\mu}. \quad (7)$$

Since the threshold energy 2ν of a Feshbach resonance depends on an external magnetic field B , Eq. (7) is tunable by adjusting B . We briefly note that this tuning mechanism uses the fact that hyperfine states of Fermi atoms confined in a Feshbach molecule (closed channel) are different from those of the incident and the outgoing atoms (open channel) shown in Fig. 1(b) (Chin et al., 2010). Their Zeeman energies then become different from each other. Because the threshold energy 2ν is directly related to the energy difference between the open channel and the closed channel, B -dependent 2ν is realized.

In the current experiments on superfluid ^{40}K and ^6Li Fermi gases, the so-called broad Feshbach resonance is always used. This resonance type is characterized by a large coupling constant g . In this case, the pairing interaction U_{FR} in Eq. (7) can be strong even when $2\nu \gg 2\mu$. Then, while a molecular boson virtually appears in the intermediate state of the Feshbach resonance (see Fig. 1(b)), the occupation number of the Feshbach-molecular band $\varepsilon_q^{\text{B}} = q^2/(2M) + 2\nu$ ($\gg 2\mu$), which is located much higher than the bottom energy of the atomic band ε_p , is negligibly small, as far as we consider the interesting BEC-BCS crossover region (Partridge et al., 2005). As a result, for the study of ^{40}K and ^6Li Fermi gases with a broad Feshbach resonance, one may use the simpler BCS model Hamiltonian,

$$H_{\text{BCS}} = \sum_{p,\sigma} \varepsilon_p c_{p,\sigma}^\dagger c_{p,\sigma} - U \sum_{p,p',q} c_{p+q/2,\uparrow}^\dagger c_{-p+q/2,\uparrow}^\dagger c_{-p'+q/2,\uparrow} c_{p'+q/2,\uparrow}, \quad (8)$$

instead of the CFB model in Eq. (1). In Eq. (8), $-U$ is *not* the fixed residual weak interaction involved in Eq. (1), but a *tunable* pairing interaction associated with a broad Feshbach resonance. Then, the superfluid state is characterized by the ordinary BCS order parameter Δ in Eq. (3). In the mean-field approximation, it obeys the BCS gap equation (Schrieffer, 1964),

$$1 = U \sum_p \frac{1}{2E_p} \tanh \frac{E_p}{2T}, \quad (9)$$

where E_p is given in Eq. (6) where the composite order parameter $\tilde{\Delta}$ is replaced by the ordinary BCS one Δ .

The above simplification is not valid for a narrow Feshbach resonance, being characterized by a small coupling g . In this case, in order for the Feshbach-induced interaction U_{FR} to be strong, one needs to lower the threshold energy 2ν down to be close to 2μ so that the denominator in Eq. (7) is much smaller than g^2 . Such a situation naturally brings about the sizable occupation of the molecular band, so that one must deal with the CFB model.

The momentum summation in the gap equation (9) exhibits ultraviolet divergence without a cutoff, because the contact-type interaction $-U$ is used in Eq. (8). Regarding this, in conventional s -wave superconductivity, the phonon-mediated pairing interaction works only near the Fermi surface within the energy range $\sim [\varepsilon_F - \omega_D, \varepsilon_F + \omega_D]$, where ε_F is the Fermi energy and ω_D ($\ll \varepsilon_F$) is related to the Debye frequency. Thus, one actually does not need to worry about this divergence, because the momentum summation in Eq. (9) is physically restricted to this energy range (which is also referred to as the BCS window in the literature).

On the other hand, such a physical cutoff is absent, or at least unclear, in the case of the Feshbach-induced pairing interaction. In this case, to remove the ultraviolet divergence from the gap equation (9), it is convenient to measure the interaction strength in terms of the observable s -wave scattering length a_s , which is related to the bare interaction $-U$ as (Randeria, 1995)

$$\frac{4\pi a_s}{m} = -\frac{U}{1 - U \sum_p \frac{1}{2\varepsilon_p}}. \quad (10)$$

Although the momentum summation in Eq. (10) diverges without a cutoff, we actually do not explicitly evaluate this equation, but 'borrow' the observed value of a_s . In this scale, the weak-coupling BCS regime and the strong-coupling BEC regime are specified as $(k_F a_s)^{-1} \lesssim -1$ and $1 \lesssim (k_F a_s)^{-1}$, respectively. The region, $-1 \lesssim (k_F a_s)^{-1} \lesssim 1$, is called the BCS-BEC crossover region. Using a_s , we obtain the *renormalized* gap equation,

$$1 = -\frac{4\pi a_s}{m} \sum_p \left[\frac{1}{2E_p} \tanh \frac{E_p}{2T} - \frac{1}{2\varepsilon_p} \right]. \quad (11)$$

The momentum summation in Eq. (11) now converges without a cutoff.

BEC-BCS crossover at $T = 0$

The BCS gap equation (11) was originally derived for the weak-coupling superconducting state. However, it can also describe the BEC-BCS crossover phenomenon at $T = 0$, at least qualitatively, if one solves Eq. (11) together with the equation for the number N of fermions in the BCS approximation,

$$N = \sum_p \left[1 - \frac{\xi_p}{E_p} \tanh \frac{E_p}{2T} \right], \quad (12)$$

to self-consistently determine Δ and μ for a given interaction strength. This approach is sometimes referred to as the BCS-Leggett theory (Leggett, 2006).

In the weak-coupling BCS limit ($(k_F a_s)^{-1} \ll -1$), Eqs. (11) and (12) give (Pethick and Smith, 2008)

$$\mu(T = 0) = \varepsilon_F (> 0), \quad (13)$$

$$\Delta(T = 0) = \frac{8}{e^2} \varepsilon_F e^{\frac{\pi}{2k_F a_s}} (\ll \varepsilon_F). \quad (14)$$

In the strong-coupling BEC limit ($(k_F a_s)^{-1} \gg +1$), on the other hand, we obtain

$$\mu(T = 0) = \frac{1}{2} E_{\text{bound}}^{2b} (< 0), \quad (15)$$

$$\Delta(T = 0) = \sqrt{\frac{16}{3\pi}} |\mu|^{1/4} e_F^{3/4} (\ll |\mu|). \quad (16)$$

Here,

$$E_{\text{bound}}^{2b} = -\frac{1}{ma_s^2} \quad (17)$$

is the energy of a two-body bound state, obtained from the following two-particle Schrödinger equation when $a_s > 0$:

$$\left[-\frac{\nabla_{\mathbf{r}_1}^2}{2m} - \frac{\nabla_{\mathbf{r}_2}^2}{2m} - U\delta(\mathbf{r}_1 - \mathbf{r}_2) \right] \Psi(\mathbf{r}_1 - \mathbf{r}_2, \sigma_1, \sigma_2) = E_{\text{bound}}^{2b} \Psi(\mathbf{r}_1 - \mathbf{r}_2, \sigma_1, \sigma_2). \quad (18)$$

In Eq. (18), the bound-state wavefunction $\Psi(\mathbf{r}_1 - \mathbf{r}_2, \sigma_1, \sigma_2)$ has the form,

$$\Psi(\mathbf{r}_1 - \mathbf{r}_2, \sigma_1, \sigma_2) = \frac{1}{\sqrt{2\pi a_2}} \frac{1}{|\mathbf{r}_1 - \mathbf{r}_2|} e^{-|\mathbf{r}_1 - \mathbf{r}_2|/a_2} |0, 0\rangle, \quad (19)$$

where $|0, 0\rangle$ is the spin-singlet state. Since the contact interaction $-U\delta(\mathbf{r}_1 - \mathbf{r}_2)$ works only when two fermions come to the same spatial position, the spin-triplet bound state is not obtained from Eq. (18).

Since the chemical potential physically means the energy to add one fermion to the system, Eq. (13) reasonably indicates the presence of a Fermi sphere in the weak-coupling limit. We also find from Eq. (15) that, when *two* fermions are added to the system deep inside the BEC regime, they immediately form a two-body bound state given in Eq. (19), so that the system energy is lowered by $2 \times \mu = E_{\text{bound}}^{2b} (< 0)$. That is, this regime may be viewed as a gas of two-body bound molecules, as expected in the BEC-BCS crossover phenomenon. The BCS-Leggett theory can really describe this feature.

Because of the sign change of the chemical potential in the BEC-BCS crossover seen in Eqs. (13) and (15), the threshold energy ($\equiv E_{\text{th}}$) of Bogoliubov single-particle excitations given in Eq. (6) changes from $E_{\text{th}} = |\Delta|$ to $E_{\text{th}} = \sqrt{\mu^2 + |\Delta|^2}$, as one moves from the BCS regime to the BEC regime. Equations (15)–(17) indicate that $|\mu| \gg |\Delta|$ in the extreme BEC limit, so that the threshold energy is eventually reduced to $E_{\text{th}} \rightarrow |\mu| = |E_{\text{bound}}^{2b}|/2$ there. Since $2 \times E_{\text{th}}$ physically means the energy to break up a Cooper pair, this result in the BEC limit is consistent with the above-mentioned picture of a gas of two-body bound molecules.

The Schrödinger equation (18) does not have a bound state solution when $a_s < 0$, which means that the interaction strength is not strong enough to form a *two-body* bound state there. As clarified by Cooper (1956), the Cooper pair in this weak-coupling regime is a *many-body* bound state, in the sense that this pair formation is assisted by the presence of a Fermi surface (Cooper instability): $E_{\text{th}} = 2|\Delta|$ physically means the binding energy of such a Fermi-surface-assisted bound state. Thus, the change, $E_{\text{th}} = |\Delta| \rightarrow |\mu|$, in the BEC-BCS crossover reflects the change of the character of a Cooper pair, from a many-body bound state to a two-body one.

BEC-BCS crossover at T_c

The mean-field based coupled gap equation (11) with the number equation (12) can also be applied to the system at non-zero temperatures in the weak-coupling BCS regime. Particularly at the superfluid phase transition temperature T_c in this regime, the number equation simply gives $\mu(T_c) \simeq \varepsilon_F$. T_c is obtained from the gap equation (11) with $\Delta = 0$ as (Pethick and Smith, 2008)

$$T_c = \frac{8\gamma}{\pi e^2} e^{\frac{\pi-1}{2\gamma a_s}}, \quad (20)$$

where $\gamma = 1.78$ is the Euler constant. The ratio of Eq. (14) to Eq. (20),

$$\frac{2\Delta(T=0)}{T_c} = \frac{2\pi}{\gamma} \simeq 3.54, \quad (21)$$

is known as the BCS universal constant. While Eq. (21) was historically used to confirm the correctness of the BCS theory, this ratio also tells us that the magnitude of T_c is comparable to the binding energy $2|\Delta(T=0)|$ of a Cooper pair at $T=0$. This physically means that the superfluid phase transition in the weak-coupling BCS regime is caused by the thermal dissociation of Cooper pairs when the temperature increases. Because of this, T_c in this regime increases with increasing the interaction strength, reflecting the increase of the binding energy of a Cooper pair.

In the strong-coupling BEC regime, most Fermi atoms form two-body bound states with the binding energy $|E_{\text{bound}}^{\text{2b}}| = 1/(ma_s^2)$, so that the resulting system may be viewed as a gas of $N_B \simeq N/2$ Bose molecules with a molecular mass $m_B = 2m$. Thus, the superfluid phase transition temperature in this regime should approach the BEC phase transition temperature T_{BEC} of such a molecular Bose gas, given by

$$T_{\text{BEC}} = \frac{2\pi}{\zeta(3/2)^{2/3}} \frac{N_B^{2/3}}{m_B} \simeq 0.218 T_F, \quad (22)$$

where $\zeta(3/2) \simeq 2.612$ is the zeta-function.

However, the mean-field based BCS-Leggett theory cannot describe this situation: While the gap equation (11) with $\Delta = 0$,

$$1 = -\frac{4\pi a_s}{m} \sum_p \left[\frac{1}{2\xi_p} \tanh \frac{\xi_p}{2T} - \frac{1}{2\varepsilon_p} \right], \quad (23)$$

gives the expected result, $\mu(T_c) = E_{\text{bound}}^{\text{2b}}/2$ (< 0), deep inside the BEC regime ($(k_F a_s)^{-1} \gg +1$), Eq. (12) at T_c is simply reduced to the number equation in a *free Fermi gas*,

$$N = 2 \sum_p f(\xi_p), \quad (24)$$

where $f(\xi_p) = 1/[e^{\xi_p/T} + 1]$ is the Fermi distribution function. Obviously, Eq. (24) cannot give T_{BEC} in Eq. (22).

This problem was solved by Nozières and Schmitt-Rink (NSR) (Nozières and Schmitt-Rink, 1985). They corrected the number equation (24) by including effects of pairing fluctuations, that are completely ignored in the mean-field scheme. On the other hand, the T_c -equation (23) remained unchanged in their theory. In this so-called NSR theory, the corrected number equation is derived from the thermodynamic identity,

$$N = -\left(\frac{\partial \Omega}{\partial \mu}\right)_{T,V}, \quad (25)$$

where the thermodynamic potential Ω involves fluctuation corrections $\delta\Omega$ which is diagrammatically given in Fig. 2(a). The resulting NSR number equation is given by Nozières and Schmitt-Rink (1985) and Ohashi et al. (2020)

Fig. 2 (a) Fluctuation correction $\delta\Omega$ to the thermodynamic potential Ω in the NSR theory. The solid line is the bare single-particle thermal Green's function G_0 , and the dashed line denotes the pairing interaction $-U$. (b) Diagrammatic representation of the particle-particle scattering matrix $\Gamma(\mathbf{q}, i\nu_n)$ in Eq. (27). (c) Self-energy Σ in a T -matrix approximation.

$$N = 2 \sum_{\mathbf{p}} f(\xi_{\mathbf{p}}) - T \sum_{\mathbf{q}, \nu_n} \Gamma(\mathbf{q}, i\nu_n) \frac{\partial \Pi(\mathbf{q}, i\nu_n)}{\partial \mu} e^{i\delta \nu_n}. \quad (26)$$

Here, $\nu_n = 2n\pi T$ is the boson Matsubara frequency (where $n = 0, \pm 1, \pm 2, \dots$) and δ is an infinitesimally small positive number. In Eq. (26), the particle-particle scattering matrix $\Gamma(\mathbf{q}, i\nu_n)$, which is given by the sum of the ladder diagrams in Fig. 2(b), describe pairing fluctuations. Summing up these diagrams, we obtain

$$\Gamma(\mathbf{q}, i\nu_n) = \frac{\frac{4\pi a_s}{m}}{1 + \frac{4\pi a_s}{m} \left[\Pi(\mathbf{q}, i\nu_n) - \sum_{\mathbf{q}} \frac{1}{2\varepsilon_{\mathbf{q}}} \right]}, \quad (27)$$

where

$$\Pi(\mathbf{q}, i\nu_n) = \sum_{\mathbf{p}} \frac{1 - f(\xi_{\mathbf{p}+\mathbf{q}/2}) - f(\xi_{-\mathbf{p}+\mathbf{q}/2})}{\xi_{\mathbf{p}+\mathbf{q}/2} + \xi_{-\mathbf{p}+\mathbf{q}/2} - i\nu_n} \quad (28)$$

is the lowest-order pair correlation function in terms of the pairing interaction.

When pairing fluctuations are weak in the weak-coupling BCS regime ($(k_F a_s)^{-1} \lesssim -1$), the last term in Eq. (26) may be safely ignored. In this case, T_c in Eq. (20) and $\mu(T_c) \simeq \varepsilon_F$ are again obtained.

In the strong-coupling BEC regime ($(k_F a_s)^{-1} \gg +1$), Eq. (23) gives,

$$\mu(T_c) \simeq \frac{1}{2} E_{\text{bound}}^2 (< 0). \quad (29)$$

Because of this negative chemical potential, the NSR number equation (26) is dominated by the second term in this regime. Deep inside the BEC regime ($(k_F a_s)^{-1} \gg +1$), Eq. (26) is reduced to

$$\frac{N}{2} = \sum_{\mathbf{q}} \frac{1}{e^{\frac{q^2}{4m}/T} - 1}. \quad (30)$$

This is just the condition for the BEC phase transition of an ideal gas of $N/2$ bosons with a Bose mass $2m$, giving the expected BEC phase transition temperature T_{BEC} in Eq. (22). By numerically solving the T_c -equation (23) together with the NSR number equation (26), the NSR theory is found to smoothly connect these two extreme results, as schematically shown in Fig. 3.

The molecular picture in the BEC regime at T_c is also valid for the normal state above T_c , because Eq. (29) indicates that molecular bosons still remain to exist even at T_c . This situation is quite different from that in the weak-coupling BCS regime, where Cooper pairs are destroyed thermally to disappear above T_c . Thus, in the strong-coupling BEC regime, single-particle excitations in the normal state near T_c are still accompanied by molecular dissociations. This situation leads to the opening of the energy gap $E_{\text{gap}} \simeq |E_{\text{bound}}^2|$ in the Fermi single-particle density of states (DOS) (Stewart, 2008), although the superfluid order parameter Δ vanishes above T_c . This gapped DOS gradually changes to the ordinary gapless one, as one passes through the BEC-BCS crossover region to approach the BCS regime. Thus, around the unitary limit ($(k_F a_s)^{-1} = 0$), DOS in the normal state exhibits a pseudogap structure near T_c being characterized by a dip structure around the Fermi level (Tsuchiya et al., 2008).

The particle-particle scattering matrix $\Gamma(\mathbf{q}, i\nu_n)$ in Eq. (27) has a pole at $\mathbf{q} = \nu_n = 0$, when Eq. (23) is satisfied at T_c . This is a direct consequence of the appearance of the gapless Nambu-Goldstone mode below T_c . However, the divergence of $\Gamma(\mathbf{q} = 0, i\nu_n = 0)$ itself does not remain after the $\mathbf{q}$ -summation is taken in Eq. (26) in three dimension, leading to non-zero T_c . In one and two dimensions, on the other hand, the second term in Eq. (26) diverges when the gap equation (23) is satisfied, leading to the vanishing T_c . This is consistent with the Hohenberg-Mermin-Wagner theorem (Hohenberg, 1967; Mermin and Wagner, 1966).

Fig. 3 Illustration of BEC-BCS crossover behavior of T_c . The region-A is considered similar to the s-wave neutron superfluid predicted in the low density crust regime of a neutron star.

The idea of NSR theory was later applied to the Green's function theory, to produce various T -matrix type BEC-BCS crossover theories (Haussmann, 1999; Kashimura, 2012; Perali et al., 2002). In these theories, the self-energy Σ having the diagrammatic structure shown in Fig. 3(c) are commonly used. For example, when the bare single-particle thermal Green's function,

$$G_0(\mathbf{p}, i\omega_n) = \frac{1}{i\omega_n - \xi_{\mathbf{p}}}, \quad (31)$$

(where $\omega_n = \pi(2n+1)T$ is the fermion Matsubara frequency, with $n = 0, \pm 1, \pm 2, \dots$) is used to construct this self-energy diagram, it is called the T -matrix approximation (TMA) (Perali et al., 2002). On the other hand, the self-consistent T -matrix approximation (SCTMA) (Haussmann, 1999) uses the dressed Green's function,

$$G(\mathbf{p}, i\omega_n) = \frac{1}{i\omega_n - \xi_{\mathbf{p}} - \Sigma(\mathbf{p}, i\omega_n)}, \quad (32)$$

to construct the self-energy. The intermediate version between the two also exists, which is sometimes referred to as the extended TMA (ETMA) (Kashimura, 2012). Apart from details, all these strong-coupling theories can describe the BEC-BCS crossover behavior of T_c shown in Fig. 3. These strong-coupling theories at T_c have also been extended to the superfluid phase below T_c (Fukushima et al., 2007; Haussmann, 2008), where phase and amplitude fluctuations of the superfluid order parameter Δ are taken into account.

Nambu-Goldstone mode

A characteristic superfluid phenomenon below T_c is the appearance of the Nambu-Goldstone mode. It is a collective phase oscillation of the superfluid order parameter Δ , and has a linear dispersion, $\omega_q = v_\phi q$, in the low-momentum region. Since the Bogoliubov single-particle excitations have non-zero energy gap (see Eq. (6)), the low-energy properties of the superfluid state are dominated by this *gapless* collective mode.

Treating the Nambu-Goldstone mode at $T = 0$ within the BCS-Leggett theory, the mode energy ω_q is obtained from the pole of the analytic continued particle-particle scattering matrix $\Gamma(q, iv \rightarrow \omega_q + i\delta)$ in Eq. (27) extended to the superfluid phase below T_c (Ohashi et al., 2020). In the weak-coupling BCS regime ($(k_F a_s)^{-1} \lesssim -1$), this so-called BCS-GRPA (generalized random phase approximation) theory gives the velocity of the Anderson-Bogoliubov mode in the neutral Fermi superfluid (Anderson, 1958),

$$v_\phi = \frac{1}{\sqrt{3}} v_F, \quad (33)$$

where v_F is the Fermi velocity. In the strong-coupling BEC regime ($(k_F a_s)^{-1} \gtrsim 1$), on the other hand, one obtains

$$v_\phi = \sqrt{\frac{U_B N_B}{m_B}}, \quad (34)$$

which is just the velocity of the collective Bogoliubov phonon in a weakly interacting Bose superfluid with $N_B = N/2$ bosons and mass $m_B = 2m$. In Eq. (34),

$$U_B = \frac{4\pi a_B}{m_B} \quad (35)$$

is an effective Bose-Bose interaction. For the value of the s -wave Bose scattering length a_B , the BCS-GRPA scheme gives $a_B = 2a_s$ (Ohashi et al., 2020), which is larger than the exact value $a_B = 0.6a_s$ obtained by solving a four-particle problem (Petrov et al., 2004). These results ($a_B > 0$) indicate that molecular bosons in the BEC regime *repulsively* interact each other, although the interaction between Fermi atoms is *attractive*. With increasing the strength of a pairing interaction, the velocity v_ϕ of the Nambu-Goldstone mode gradually decreases from Eq. (33), to eventually vanishes in the extreme BEC limit ($(k_F a_s)^{-1} \rightarrow +\infty$), where the system is simply described by an ideal molecular Bose gas.

In the weak-coupling BCS regime, when the mode energy ω_q approaches the excitation threshold $2|\Delta|$ of the two-particle continuum (which physically describe the dissociations of Cooper pairs), level repulsion occurs between them, which makes the mode dispersion a convex upward function. Deep inside the BEC regime ($\mu < 0$), on the other hand, the threshold energy ($= 2\sqrt{\mu^2 + |\Delta|^2} \rightarrow 2|\mu|$) of the two-particle continuum is very high, so that the Nambu-Goldstone mode is not affected by this threshold energy. As a result, the mode dispersion in the BEC regime has the same form as that of the Bogoliubov phonon (Pethick and Smith, 2008),

$$\omega_q = \sqrt{\frac{q^2}{2m_B} \left[\frac{q^2}{2m_B} + 2U_B N_B \right]}, \quad (36)$$

which is a convex downward function. Thus, starting from the weak-coupling BCS regime, the dispersion of the Nambu-Goldstone mode changes from a *convex upward* function to a *convex downward* one, as one passes through the BEC-BCS crossover region. Such a change of the mode dispersion in the BEC-BCS crossover region has been observed in a superfluid ^6Li Fermi gas (Biss et al., 2022).

Since the low-energy excitations in the superfluid state is dominated by the gapless Nambu-Goldstone mode, the fact that it always has a linear dispersion around $q = 0$ in the whole BEC-BCS crossover region is crucial for the *superfluidity* of the system: According to the Landau criterion, the supercurrent state is stable, when the current velocity V_{sc} satisfies

$$|V_{sc}||q| < \omega_q. \quad (37)$$

Indeed, Eq. (37) guarantees non-zero critical velocity of the supercurrent state in the case when ω_q has a linear dispersion around $q = 0$, unless ω_q vanishes at a non-zero q . We briefly note that Eq. (37) is obtained from the condition that the supercurrent state is stable against a low-energy excitation with the energy ω_q and the momentum q (Ohashi et al., 2020). That is, the energy $E_{sc} = M_{sys}V_{sc}^2/2$ in this supercurrent state (where M_{sys} the total mass of the system) must be always lower than the energy in the excited state as

$$\frac{1}{2}M_{sys}V_{sc}^2 < \frac{1}{2}M_{sys}\bar{V}_{sc}^2 + \omega_q \quad (38)$$

where the current velocity $\bar{V}_{sc}$ in the excited state satisfies the momentum conservation,

$$M_{sys}V_{sc} = M_{sys}\bar{V}_{sc} + q. \quad (39)$$

Under the assumption that the system mass M_{sys} is huge, Eq. (38) immediately gives Eq. (37).

We note that the Nambu-Goldstone mode with a linear dispersion does not exist in the ground state of metallic superconductivity. In this case, the long-range Coulomb interaction between electrons pushes this gapless mode up to the gapped plasma mode (Anderson-Higgs mechanism) (Anderson, 1963),

$$\omega_{p1} = \sqrt{\frac{4\pi Ne^2}{m}}. \quad (40)$$

Just below T_c , however, the gapless collective mode revives even in superconductivity, because quasi-particles excited thermally (that are actually Bogoliubov single-particle excitations) screen the long-range Coulomb interaction between superconducting electrons, so that the Anderson-Higgs mechanism no longer works. This revived Nambu-Goldstone mode in superconductivity is known as the Carlson-Goldman mode (Carlson and Goldman, 1975; Ohashi and Takada, 1997).

Tan's contact

When the system is described by the BCS Hamiltonian in Eq. (8) with no high-momentum cutoff, Tan proved that the internal energy E can be written as (Tan, 2008a)

$$E = 2 \sum_p \epsilon_p \left[n_p - \frac{C}{p^4} \right] + \frac{C}{4\pi m a_s}, \quad (41)$$

where C is called the Tan's contact, which is obtained from the high momentum behavior of the momentum distribution $n_p = \langle c_{p,\sigma}^\dagger a_{p,\sigma} \rangle$ as

$$n_p \xrightarrow{p \rightarrow \infty} \frac{C}{p^4}. \quad (42)$$

The Tan's contact C vanishes in a free Fermi gas, because n_p is just the Fermi distribution function in this case. Thus, C is related to correlation effects. Since ^{40}K and ^6Li Fermi gases with a broad Feshbach resonance are well described by the BCS model in Eq. (8), this quantity in the BEC-BCS crossover region has attracted much attention in cold Fermi gas physics.

Although the BCS-Leggett theory is an approximate theory, it still satisfies the exact expression in Eq. (41): In the mean-field BCS approximation, one finds,

$$n_p = 1 - \frac{\xi_p}{E_p} \xrightarrow{p \rightarrow \infty} \frac{m^2 \Delta^2}{p^4}, \quad (43)$$

which immediately gives

$$C = m^2 |\Delta|^2. \quad (44)$$

It can be shown that the BCS ground state energy,

$$E = \sum_p \left[\xi_p - E_p + \frac{\Delta^2}{2E_p} \right] + \mu N - \frac{m}{4\pi a_s} |\Delta|^2, \quad (45)$$

can be rewritten as Eq. (41), when Eq. (44) is used.

In the unitary limit ($(k_F a_s)^{-1} = 0$) at $T = 0$, Eq. (44) gives $C \simeq 0.12 k_F^4$ (Ohashi et al., 2020), which is close the experimental result, $C \simeq 0.1 k_F^4$, observed in a ^6Li superfluid Fermi gas (Horikoshi et al., 2017).

Tan also derived the following *adiabatic sweep theorem* (Tan, 2008b),

$$\left(\frac{\partial E}{\partial a_s^{-1}} \right)_N = -\frac{C}{4\pi m}, \quad (46)$$

as well as the *pressure relation*,

$$P = \frac{2}{3}E + \frac{C}{12\pi m a_s}. \quad (47)$$

These exact equations are also satisfied in the BCS-Leggett theory, when Eq. (44) is used (Ohashi et al., 2020).

Unitary Fermi gas and universal thermodynamics

The unitary limit, which is characterized by the diverging scattering length $a_s \rightarrow \pm\infty$ (or $(k_F a_s)^{-1} = 0$), is located just in the center of the BEC-BCS crossover phase diagram shown in Fig. 3. Since this regime is dominated by strong pairing fluctuations caused by the strong attractive interaction, various interacting many-body phenomena, such as the pseudogap, have been discussed (Zwerger, 2012).

At this special interaction strength ($a_s^{-1} = 0$), we can no longer use the scattering length a_s as a length scale of the system. The remaining relevant length scales are the thermal de Broglie length,

$$\lambda_T(T) = \sqrt{\frac{2\pi}{mT}}, \quad (48)$$

and the inter-particle distance $l \propto \rho(\mu)^{-1/3}$, where

$$\rho(\mu) = \frac{(2m\mu)^{3/2}}{3\pi^2} \quad (49)$$

is the number density of an assumed free Fermi gas with the Fermi energy μ . Using these, Ho proposed the hypothesis that the thermodynamic potential Ω in a unitary Fermi gas may be scaled by these parameters as (Ho, 2004), for example,

$$\Omega(T, \mu, V) = \mu V \rho(\mu) g_\mu\left(\frac{\mu}{T}\right), \quad (50)$$

and

$$\Omega(T, \mu, V) = T \frac{V}{\lambda_T^3(T)} g_T\left(\frac{\mu}{T}\right), \quad (51)$$

where $g_\mu(x)$ and $g_T(x)$ are dimensionless functions. Using Eq. (51), one obtains the particle number N and the entropy S as, respectively,

$$N = -\left(\frac{\partial \Omega}{\partial \mu} \right)_{T,V} = -\frac{V}{\lambda_T^3} \left(\frac{\partial g_T(x)}{\partial x} \right)_{x=\mu/T}, \quad (52)$$

$$\begin{aligned} S &= -\left(\frac{\partial \Omega}{\partial T} \right)_{\mu,V} \\ &= -\frac{5}{2} \frac{V}{\lambda_T^3} g_T\left(\frac{\mu}{T}\right) + \frac{\mu}{T} \frac{V}{\lambda_T^3} \left(\frac{\partial g_T(x)}{\partial x} \right)_{x=\mu/T}. \end{aligned} \quad (53)$$

Substituting Eqs. (51)–(53) into the thermodynamic identity,

$$\Omega = -PV = E - TS - \mu N, \quad (54)$$

we obtain the well-known expression in a free Fermi gas,

$$E = \frac{2}{3}PV, \quad (55)$$

in spite of the fact that we are considering a strongly interacting unitary Fermi gas. Equation (55) is universal in the sense that it holds at arbitrary temperatures in the unitary limit, irrespective of whether the system is in the superfluid state or in the normal state. Equation (55) also agrees with the exact pressure relation in Eq. (47) when $a_s^{-1} \rightarrow 0$.

At $T = 0$, using Eq. (54) with $S(T=0) = 0$, we also obtain

$$E = \frac{3}{5}N\mu \equiv \frac{3}{5}\xi_B N \epsilon_F, \quad (56)$$

where $\xi_B = \mu/\epsilon_F$ is called the Bertsch parameter, describing correlation effects in the ground state of a unitary Fermi gas. The BCS-Leggett theory gives $\xi_B \simeq 0.6$, which is larger than the experimental result, $\xi_B \simeq 0.375$, on a ${}^6\text{Li}$ unitary Fermi gas (Horikoshi et al., 2017). The T -matrix theories give better results, $\xi_B = 0.36\text{--}0.45$, depending on detailed approximations (Ohashi et al., 2020).

Neutron superfluid in the crust regime of neutron star

It is expected that the region-A in Fig. 3 ($(k_F a_s)^{-1} \ll 1$ and $T \ll T_c$) is similar to the s -wave neutron superfluid state predicted in the low-density crust regime of a neutron star. Since the neutron number density ($\rho_N \propto k_F^3$) increases as one goes inside the neutron star, the scaled interaction $(k_F a_s)^{-1}$ varies, in spite of the fixed value of the neutron s -wave scattering length $a_s \simeq -18.5$ fm. This is the reason why the region-A in Fig. 3 extends laterally.

However, we cannot immediately employ the results obtained in this regime of superfluid ${}^{40}\text{K}$ and ${}^6\text{Li}$ Fermi gases for the study of the neutron superfluid, because the importance of the effective range r_{eff} is different between the two systems: While it is negligibly small in ${}^{40}\text{K}$ and ${}^6\text{Li}$ Fermi gases, it cannot be ignored in the neutron superfluid, because $r_{\text{eff}} \simeq 2.7$ fm there (which gives $(k_F r_{\text{eff}}) \simeq 2.7$ for the typical value $k_F = 1 \text{ fm}^{-1}$ in the crust regime). Thus, in order to study the latter nuclear matter, we need to extend the strong-coupling theories developed in cold Fermi gas physics to the case with $r_{\text{eff}} \neq 0$.

To deal with the effective range r_{eff} , it is convenient to replace the contact-type pairing interaction $-U$ involved in Eq. (8) by a momentum dependent one $-\tilde{U}(\mathbf{p} - \mathbf{p}')$. Within the effective range theory, r_{eff} can conveniently be incorporated into the theory by approximating $-\tilde{U}(\mathbf{p} - \mathbf{p}')$ to the following separable form in considering the Cooper channel:

$$-\tilde{U}(\mathbf{p} - \mathbf{p}') \rightarrow -\tilde{U}(0)\gamma_{\mathbf{p}}\gamma_{\mathbf{p}}'. \quad (57)$$

Here, the basis function $\gamma_{\mathbf{p}}$ has the form,

$$\gamma_{\mathbf{p}} = \frac{1}{\sqrt{1 + (p/p_c)^2}}. \quad (58)$$

The relation between the s -wave scattering length a_s and the BCS coupling constant $-U$ in Eq. (10) is replaced by

$$\frac{4\pi a_s}{m} = -\frac{\tilde{U}(0)}{1 - \tilde{U}(0)\sum_{\mathbf{p}} \frac{\gamma_{\mathbf{p}}^2}{2\epsilon_{\mathbf{p}}}} = -\frac{\tilde{U}(0)}{1 - \tilde{U}(0)\frac{mp_c}{4\pi}}. \quad (59)$$

In the two-particle limit, setting

$$P_c = \frac{1}{r_{\text{eff}}} \left[\sqrt{1 - \frac{2r_{\text{eff}}}{a_s}} + 1 \right], \quad (60)$$

we obtain the ordinary expression for the s -wave scattering amplitude $f_s(p)$ in the effective range theory (van Wyk et al., 2018),

$$f_s(p) = \frac{1}{-\frac{1}{a_s} + \frac{1}{2}r_{\text{eff}}p^2 - ip}. \quad (61)$$

When the pairing interaction is replaced by Eq. (57) in the BCS-Leggett theory, the number equation (12) remains unchanged, except that superfluid order parameter Δ involved in $E_p = \sqrt{\epsilon_p^2 + |\Delta|^2}$ is replaced by the momentum-dependent one,

$$\Delta_p = \gamma_p \Delta. \quad (62)$$

The gap equation (11) is replaced with

$$1 = \tilde{U}(0)\sum_{\mathbf{p}} \frac{\gamma_{\mathbf{p}}^2}{2E_p}. \quad (63)$$

In the case of Eq. (10) where the momentum summation diverges, the strength of the bare interaction strength $-U$ should be considered infinitesimally small. Because of this, in the BCS-Leggett theory explained in Sec. II-B has no Hartree term. On the other hand, Eq. (59) gives $-\tilde{U}(0) \neq 0$, leading to non-zero Hartree energy $\Sigma_H = -\tilde{U}(0)N_{\text{MF}}/2$ (where N_{MF} is the number of Fermi atoms in the mean-field approximation). When this effect is taken into account, the Fermi chemical potential μ involved in the gap equation (63) and the number equation (12) is replaced by $\tilde{\mu} = \mu - \Sigma_H$.

The gap equation (63) indicates that r_{eff} effectively gives a (smooth) momentum cutoff, above which the pairing interaction is weak. Regarding this, we note that, while the cutoff ω_D in conventional superconductivity determines the region where the phonon-mediated pairing interaction works around the Fermi level $\sim [\epsilon_F - \omega_D, \epsilon_F + \omega_D]$, the present cutoff coming from the effective range r_{eff} does not depend on the Fermi level. As a result, when $p_c \gg k_F$ in the low density region, the situation is close to the case of ultracold Fermi gases (where $p_c \rightarrow \infty$, see also Eq. (10)). On the other hand, the pairing interaction around the Fermi level becomes weak, when $p_c \ll k_F$ in the high-density region. In this case, we cannot ignore effects of the effective range on the pairing phenomenon.

In the s -wave neutron superfluid ($a_s \simeq -18.5$ fm and $r_{\text{eff}} \simeq 2.7$ fm), Eq. (60) is evaluated as

$$p_c \simeq 0.79 \text{ fm}^{-1}. \quad (64)$$

Thus, we expect that the cold Fermi gas system can be used as a quantum simulator for the study of the neutron superfluid in the low-density region satisfying $p \lesssim 0.79 \text{ fm}^{-1}$. Indeed, it has been shown that the superfluid NSR theory including the effective range well reproduces the equation of states of a neutron star predicted by using realistic nucleon-nucleon interactions, up to $k_F \simeq 1 \text{ fm}^{-1}$ (van Wyk et al., 2018).

When one goes deeper inside a neutron star ($k_F \gtrsim 1 \text{ fm}^{-1}$), the s -wave interaction gradually becomes less dominant. Instead, more complicated interactions, such as a p -wave and a d -wave ones, appear. At this stage, the simplest s -wave superfluid state has been realized in ultracold Fermi gases. Thus, it seems difficult to simulate the deeper inside a neutron star in the current stage of cold Fermi gas physics.

Conclusion

The BEC-BCS crossover phenomenon enables us to study how a Fermi superfluid continuously changes to a Bose superfluid, as the strength of a Fermi-Fermi attractive interaction increases. In a sense, this many-body phenomenon provides a unified description of these superfluids that are usually discussed in different physical systems. A tunable pairing interaction associated with a Feshbach resonance is a crucial key in realizing this phenomenon in ultracold ^{40}K and ^6Li Fermi gases.

Although the mean-field BCS theory was originally invented to describe weak-coupling superconductivity, it can actually cover the whole BEC-BCS crossover region at $T = 0$, when strong-coupling corrections to the Fermi chemical potential is taken into account. At non-zero temperatures, especially at T_c , however, we need to include effects of pairing fluctuations beyond the mean-field level.

The s -wave neutron superfluid predicted in the low-density crust regime of a neutron star is considered to be close to a unitary Fermi superfluid far below T_c . Thus, although the importance of the effective range is different between this neutron superfluid and superfluid ^{40}K and ^6Li Fermi atomic gases, the latter atomic system may be used as a quantum simulator for the study of the former nuclear matter in the low density region ($k_F \lesssim 1 \text{ fm}^{-1}$).

We finally list some future directions:

1. At present, the simplest s -wave superfluid has only been realized in ultracold Fermi gases. Since various non s -wave Fermi superfluids are known in superconductivity, liquid ^3He , as well as deep inside neutron stars, the realization of unconventional pairing states is an important challenge in cold Fermi gas experiment. Once an unconventional superfluid Fermi atomic gas is realized by using a non s -wave Feshbach resonance, we would again be able to examine properties of this state from the weak-to strong-coupling regime, as in the s -wave case.
2. Although we now have various strong-coupling theories that can describe the BEC-BCS crossover phenomenon, their treatments of the correlation between Cooper pairs in the strong coupling BEC regime have still room for improvement (Petrov et al., 2004). In addition, when we simply extend the NSR theory and T -matrix theories to the superfluid phase below T_c , it is known that they unphysically give the first-order phase transition in the strong-coupling BEC regime (Fukushima et al., 2007). These remain to be solved in BEC-BCS crossover theory.
3. Recently, the BEC-BCS crossover has experimentally been discussed in various metallic superconductors (Kasahara et al., 2014; Nakagawa et al., 2022; Suzuki et al., 2022). The possibility of crossover phenomenon has also been discussed in non-equilibrium exciton-polariton condensate (Yamaguchi et al., 2012). It would also be an crucial issue to explore how to use the highly tunable ultracold Fermi gas system as a quantum simulator for the studies of these newly developing BEC-BCS crossover systems.

Abstract

Neutron and proton components of matter in neutron stars become superfluid and superconducting respectively, by forming Cooper pairs. In this contribution, we provide a concise overview of the current state and open questions in the area of superfluidity and superconductivity in neutron stars, including the microscopic quantum many-body theories and their methods, physics at the meso-scale associated with the quantum vorticity and, finally, the effects of superfluidity on the macroscopic manifestations in neutron stars.

Key points

- Neutron star internal structure, superconducting and superfluid phases.
- Many-body methods of solving the Cooper pairing problem.
- Quantum vortices and flux tubes in rotating and magnetized neutron stars.
- Some open problems from the micro- to macro-scales and interpretations of observations.

Introduction

Neutron stars are often viewed as low-temperature laboratories for studies of phenomena in strongly interacting quantum many-particle systems, which are encountered in a variety of terrestrial condensed matter systems. In reviewing their physics below we will emphasize the key milestones, the recent developments, and the open issues. For a more comprehensive coverage of the topic see our recent review (Sedrakian and Clark, 2019), as well as earlier alternatives which place emphasis on varied aspects of pairing phenomena (Lombardo and Schulze, 2001; Dean and Hjorth-Jensen, 2003; Takatsuka and Tamagaki, 1993). Among the many parallels between neutron stars and condensed matter systems, one could highlight the formation of quantized vortices in neutron matter in response to stellar rotation (Ginzburg, 1969; Baym et al., 1969b) in analogy to rotating liquid Helium-II (Khalatnikov, 1989; Hall and Vinen, 1956), emergence of quantized flux-tubes in the proton superconductor (Baym et al., 1969a) in analogy to the type-II superconductors in metals (Abrikosov, 1988), spin-1 pairing in high-density neutron matter (Takatsuka and Tamagaki, 1971) in analogy to the A-phase of liquid ^3He (Volovik, 2009), and mutual entrainment of neutron-proton condensates (Sedrakian and Shakhbasian, 1980; Alpar et al., 1984) in analogy to the mixtures of superfluid ^3He and ^4He (Andreev and Bashkin, 1976).

Nucleonic Fermi liquids of neutrons (n) and protons (p) can be found in a neutron star's inner crust and outer core, where neutrons and a small fraction ($\leq 10\%$) of protons and electrons coexist under the conditions of charge neutrality and β equilibrium with respect to neutron decay $n \rightarrow p + e + \bar{\nu}$ and electron-capture processes $p + e \rightarrow n + \nu$. Here, e , ν , and $\bar{\nu}$ stand for electrons, neutrinos, and anti-neutrinos; see Fig. 1 for an illustration. Due to the attractive component of the nuclear force, neutrons and protons form Cooper pairs on their respective Fermi surfaces in analogy to the Bardeen-Cooper-Schrieffer (BCS) mechanism of superconductivity. While the induced interaction is an important factor in determining the magnitude of the gap in the neutron and

Fig. 1 Schematic interior of a neutron star of mass $M = 1.4M_\odot$ with its four basic regions: outer and inner crusts and outer and inner cores. The four shells are identified along with the values of their respective outer radii r . Also indicated are the corresponding transition densities in units of n_0 , as well as the particle content and condensates that may exist within each shell. Note that the figure is not to scale, low- n /large- r domains being strongly expanded.

proton quasiparticle spectra, its role is less crucial compared to the situation in metals, because of the attractive interaction between nucleons in the free space as opposed to e - e repulsion. Neutron-proton pairing is strongly suppressed by the large difference in the Fermi energies of neutrons and protons. The nucleon-nucleon potentials are analyzed in terms of their partial-wave components: in the low density (low energy) regime the dominant attractive interaction among neutrons, as well as protons, is in the 1S_0 partial-wave channel. This remains the case roughly up to the saturation density of nuclear matter, $n_0 \simeq 0.16 \text{ fm}^{-3}$. At higher densities the most attractive channel is the coupled 3P_2 - 3F_2 channel. It is worth noting that in isospin-symmetric nuclear matter with equal number of protons and neutrons, the dominant interaction channels in free space are the 3S_1 - 3D_1 and 3D_2 channels at low and high energies. The characteristic scale of pairing gaps is of the order of 1 MeV, which is much larger than the characteristic temperature of mature neutron stars ($T \simeq 10^8 \text{ K}$, $1 \text{ MeV} = 1.16 \cdot 10^{10} \text{ K}$). Accordingly, neutron and proton superfluids can be treated effectively in the low-temperature limit. Fig. 1 shows schematically the structure of a neutron star and the location of various superfluid and superconducting phases.

There exists significant observational evidence for superfluidity of nucleonic components in neutron stars. The pulsed emission of pulsars (with periods of from milliseconds to several seconds) is caused by the periodic rotation of the star. This makes them nearly perfect clocks, but energy losses increase the rotational periods of pulsars over secular timescales. However, some pulsars undergo abrupt increases (glitches) in their rotation and spin-down rates that are followed by slow relaxation toward their pre-glitch values (in some cases with some permanent shift of either sign in the asymptotic values). These relaxations take place on a time scale of order weeks to years. A regularly glitching pulsar is the Vela pulsar, with typical changes in the spin $\Delta\nu/\nu \simeq 10^{-6}$ and spin-derivative $\Delta\dot{\nu}/\dot{\nu} \simeq 10^{-2}$. Another prominent pulsar in the Crab nebula shows smaller glitches with $\Delta\nu/\nu \simeq 10^{-8}$ (Espinoza et al., 2011). The long relaxations after glitches are commonly attributed to components within the star that are only weakly coupled to the rigidly rotating non-superfluid component, to which the emission of pulsed radiation is locked. Candidates for such a phase are various neutron superfluid components the core or in the crust (Haskell and Melatos, 2015; Haskell and Sedrakian, 2018; Andersson, 2021). Another (indirect) source of evidence for superfluidity of neutron star interiors is their cooling evolution over long time-scales of order of millions of years. Modeling of this process shows that the suppression of the specific heat of the nucleonic component by the gaps in the neutron and proton quasiparticle spectra and additional neutrino emission due to Cooper pair-breaking processes are necessary for a proper account of the available data on the surface temperatures of neutron stars (Yakovlev et al., 2001; Page et al., 2013; Sedrakian, 2007; Schmitt and Shternin, 2018).

Natural units $\hbar = c = k_B = 1$ will be used throughout.

Overview

Microscopic theories

The main challenge of computation of parameters of nucleonic superfluids and superconductors lies in the fact that nucleons form a strongly interacting system. Variety of microscopic methods have been employed to compute, most notably, the gap in the quasiparticle spectrum. At the *mean-field BCS level* and in the energy range where the interactions are well constrained by the elastic nucleon-nucleon scattering data, i.e., for laboratory energies $E_{\text{lab.}} < 350 \text{ MeV}$, the gap can be computed from the interaction in a given partial wave (Sedrakian and Clark, 2019). In the case of an S-wave interaction $v_0(p, p')$, where p and p' are the magnitudes of the relative incoming and outgoing momenta of the particles, the gap equation reads

$$\Delta(p) = -\frac{1}{V} \sum_{p'} v_0(p, p') \frac{\Delta(p')}{2E(p')} [1 - 2f(p')], \quad (1)$$

where V is the volume, $E(p) = \sqrt{\varepsilon(p)^2 + \Delta(p)^2}$ is the quasiparticle energy, composed of the gap $\Delta(p)$ and the particle energy $\varepsilon(p)$ in the unpaired state, while $f(p) = (e^{E(p)/T} + 1)^{-1}$ is the Fermi distribution function at temperature T . Mean-field computations of the gap with high-precision nuclear potentials lead to identical results for the gap function in the low-density S-wave paired superfluid and for wave superfluids up to the energy at which the elastic phase-shifts are accurate. Apart from these, effective interactions such as the so-called Skyrme and Gogny forces have been employed with similar results (Su et al., 1987; Sedrakian et al., 2003; Allard and Chamel, 2022).

Computation beyond mean-field level has focused mainly on two issues (i) Inclusion of correlations beyond mean-field in the self-energies of the nucleons, which are often encompassed in their effective masses, accounting for the momentum and energy dependence of the self-energy. The momentum dependence of the interaction leads to an effective mass in the range $m^*/m \simeq 0.8 - 0.6$ for neutron matter at low and intermediate densities ($n/n_0 \sim 0.5-2$), with similar values also for the dilute proton component at somewhat higher densities. The energy-dependent effective mass (inverse of wave-function renormalization) is close to unity and has less dramatic effect on the gap (Cao et al., 2006; Baldo and Schulze, 2007). (ii) Inclusion of the long-range correlations in the effective pairing interaction, which typically requires summation of polarization graphs; hence these corrections are often called “polarization” effects (Clark et al., 1976). They have been found to significantly reduce the gap by factors 50% and more (Cao et al., 2006; Rios et al., 2017; Urban and Ramanan, 2020).

The theories beyond mean field have been formulated using various many-body theories, which we sketch briefly below. The early work concentrated on the correlated basis function (CBF) theory (Clark, 2013). In this theory the correlations are built in the normal-state description of a strongly interacting Fermi system through the action of a correlation operator on the mean-field state. Pairing correlations are then superimposed on the correlated normal ground state, utilizing the BCS theory approach. This method allows one to sum up and include, in a parquet manner (Jackson et al., 1982, 1985) large classes of cluster diagrams in both particle-particle and particle-hole channels, albeit this requires some averaging procedure. In recent years this approach has been applied to low-density neutron matter (Fan and Krotscheck, 2019; Krotscheck and Wang, 2021; Krotscheck and Wang, 2022).

Various Monte Carlo approaches to the problem have focused mainly on finding the correlated ground state of the normal state. In practice, an infinite system is simulated in a finite box containing a fixed number of particles subject to periodic boundary conditions. The pairing gap is then obtained from the energy difference between systems with odd and even particle numbers. These computations typically involve solutions of the non-relativistic Schrödinger equation using stochastic sampling of configurations, as the system is advanced in imaginary time. Recent work has concentrated on the Green Function Monte Carlo (GFMC) and Auxiliary Field Diffusion Monte Carlo (AFDMC) algorithms (Carlson et al., 2012; Gandolfi et al., 2022). The latest GFMC computations of bulk energy and pairing gaps in nuclear matter have been performed for systems of 60 nucleons. The self-consistent Green functions (SCGF) method (Ding et al., 2016; Rios et al., 2017) solves for the spectral function of a strongly interacting Fermi system in the normal state, thus taking into account the full off-shell features of the real and imaginary parts of the nucleon self-energy. The spectral functions are then also inserted into the BCS-type gap equation, which can be re-written in terms of normal and anomalous Greens functions featuring the normal-state spectral function. It should be noted that when detailed comparisons are appropriate, there is satisfactory agreement between the most recent CBF gap calculations (Fan and Krotscheck, 2019; Krotscheck and Wang, 2021; Krotscheck and Wang, 2022) and the 1S_0 gap in pure neutron matter and corresponding Monte Carlo results (Carlson et al., 2012; Gandolfi et al., 2022).

Fermi-liquid methods have been employed for several decades to assess the important effect of polarization of the medium on the value of the gap. Various studies have converged to the assessment that the mean-field gap in neutron matter, which is of the order of 1 MeV, is reduced by factors of the order of 2–3. (Wambach et al., 1993; Schulze et al., 2001; Urban and Ramanan, 2020).

Imbalanced pairing

Imbalanced pairing has been studied in metals since shortly after the formulation of the BCS theory in 1956. A new class of superconductors and superfluids arises when the pairing is between fermions that are on different Fermi surfaces. This is a generic situation in many contexts. In condensed matter systems, a superconductor placed in a spin-polarizing magnetic field, causing an imbalance between the number of spin-up and spin-down electrons is a good example. (Note that in fact the magnetic field mimics the polarizing effect of magnetic impurities in a metal). In nuclear physics, imbalanced pairing occurs, for example, for neutron-proton Cooper pairs in isospin asymmetric matter (i.e., for unequal numbers of protons and neutrons). Similar physics governs the pairing when neutrons (or protons) are placed in a strong magnetic field and the pairing is among spin-up and spin-down neutrons (or protons) (Stein et al., 2016). In condensed-matter systems, imbalanced pairing has been considered in the weak-coupling formalism, where the back-reaction of the pairing on the chemical potentials of particles is ignored. The imbalance was found to suppress pairing, the maximal value of the shift in the chemical potentials of two species being $\Delta(0)/\sqrt{2}$, where $\Delta(0)$ is the pairing gap in a balanced system. This limit is known as the Chandrasekhar-Clogston limit (Abrikosov, 1988). In the context of neutron-proton pairing, this back-reaction has been taken into account, leading notably to a continuous change in the gap as a function of density asymmetry (Stein et al., 2014). The ground state of an imbalanced superfluid can break translational or rotational symmetries if the imbalance is large enough. Breaking of translational invariance was first proposed and studied independently by Fulde and Ferrell (1964) and Larkin and Ovchinnikov (1965), (FFLO) who discovered that the superconducting state where the Cooper pairs carry a finite center of mass momentum can sustain imbalances beyond those given by

Fig. 2 Phase diagram of dilute nuclear matter in the temperature-density plane for several isospin asymmetries $\alpha = (n_n - n_p)/(n_n + n_p)$, where $n_{n/p}$ are the neutron and proton densities (Stein et al., 2014). The density is normalized by the nuclear saturation density n_0 . For each fixed value of α there are two tri-critical points, the point bordering the FFLO phase always being a Lifshitz point. In a special case the tri-critical points merge into a tetra-critical point (square dot). The FFLO phase disappears in the low-density regime (the limiting value being shown by a triangle). The transition from BCS pairing to BEC occurs on the vertical lines located around $\log_{10}(n/n_0) = -2$.

Chandrasekhar-Clogston limit. An alternative to the FFLO phase invokes deformations of the Fermi surfaces of the fermion species from spherically symmetric to ellipsoidal form (Müther and Sedrakian, 2002, 2003). Another possibility is the separation of phases, originally suggested in the context of cold atomic gases (Bedaque et al., 2003) and studied thereafter in infinite nuclear matter under isospin asymmetry (Stein et al., 2014). When these various phases are studied simultaneously, it turns out that the phase diagram of dilute nuclear matter features BCS type pairing at temperatures close to the critical one, but develops various types of symmetry-broken phases at lower temperatures: the phase diagram then features tri-critical points, with at least one being a Lifshitz point (Stein et al., 2014), as seen in Fig. 2. Finally, let us note that nuclear systems may feature a transition from BCS pairing to Bose-Einstein condensation (BEC) as the system transitions from high to low density (Lombardo et al., 2001). The interplay between the BCS-BEC transition and imbalanced pairing demonstrates that the low-density and low-temperature limit features only a phase-separated imbalanced phase, whereas the phases with broken symmetries, as genuinely Fermi-surface phenomena, disappear (Stein et al., 2014). In closing, we note that imbalanced superfluids have been studied experimentally in ultracold atomic gases (Schunck et al., 2007). These systems allow for an unprecedented control over the parameters of the system, including the strength of the interaction via Feshbach resonance, size of the system, relative number of spin-up and -down particles, etc.

Quantized vorticity and rotation of neutron superfluids

Neutron stars contain an array of quantum vorticity in the neutron superfluid which emerges in response to the stellar rotation, in full analogy to terrestrial superfluids such as the Bose-condensed superfluid ^4He , fermionic superfluid ^3He , or dilute Bose or Fermi quantum gases. The rotational frequencies of neutron stars (pulsars) are well within the range between the lower and upper critical velocities for the formation and destruction of vorticity. Therefore we expect that the neutron fluid is generically threaded by an array of vortices with number density per unit area and triangular lattice basis vector given by

$$n_n^{(V)} = \frac{2\Omega}{\kappa}, \quad d_n = \left(\frac{\kappa}{\sqrt{3}\Omega} \right)^{1/2}, \quad (2)$$

where $\kappa = \pi/m_n$ is the quantum of circulation, m_n is the neutron mass, and Ω is the angular velocity. The inter-vortex distance is of the order of $d_n \sim 10^{-4}$ cm for rotation periods of the order of a fraction of second. This characteristic scale is much larger than the microscopic length scales associated with the nuclear interaction and nuclear clusters (of the order 10 fm), but are much smaller than the macroscopic scales characterizing the sizes of the various regions (of the order of km). Thus the quantum vorticity defines a new *mesoscopic scale* for the description of neutron-star superfluids. Note that the macroscopic hydrodynamics requires an averaging over a large number of vortices. Interestingly, the vortex core size given by the coherence length $\xi \sim 10$ fm of the superfluid is microscopic. In the range $r \leq \xi$, where r is the radial cylindrical coordinate, the order parameter of the superfluid is suppressed linearly for $r \rightarrow 0$, vanishing at its center.

Microscopically, the core of a vortex contains specific excitations – a quasiparticle bound state described by the microscopic Bogolyubov-De Gennes (BdG) theory (de Gennes, 1999; Caroli et al., 1964; Yu and Bulgac, 2003). The solutions of these equations, in the simplest case of an S-wave superfluid in the cylindrical symmetry, show that their states are plane waves along the vortex circulation, but are quantized in the orthogonal direction. In the case of a P-wave superfluid, the vortex solutions have been studied within the Ginzburg-Landau theory, suitably generalized to spin-1 pairing. The solutions in the case have quite complex features, which include not only vortices but also domain walls (Masaki et al., 2022; Kobayashi and Nitta, 2022).

The rotational dynamics of neutron stars, notably their short-term behavior during glitches and post-glitch relaxation is controlled, to a large extent, by the dynamics of neutron vortices and their interactions with the ambient matter (Haskell and Sedrakian, 2018). Much attention has been paid to the idea of pinning of neutron vortices to nuclei in the inner crust, as seen in Fig. 1, and to their dissipative motion through it due to their quantum and thermally activated creep in analogy with the resistive state of type-II superconducting metals (Anderson and Itoh, 1975). Under a stationarity assumption, a first estimate of the pinning energy can be obtained by comparing the energy difference between a configuration where nucleus and vortex are well separated, with a configuration in which they intersect. More sophisticated approaches are based on microscopic solutions of the BdG equations (Wlazlowski et al., 2016; Bulgac, 2019).

Independent of the nature of the friction between the vortices and the normal fluid(s), a generic model of two-component star can be developed with a single superfluid and normal component, which provides qualitative understanding of the post-glitch relaxations of pulsars (Sedrakian and Sedrakian, 1995). The model is valid as long as the friction is linear in the velocity differences between the superfluid and the normal components (this may not be the case in some pinning models). More sophisticated models can be built upon assuming several superfluid shells with different moments of inertia and friction coefficients (Sedrakian et al., 1995). The fits to the post-glitch data allow one to fix these parameters in a model-independent manner (again assuming forces linear in velocities).

In the core of the star, the coexistence of the neutron and proton superfluids leads to their mutual entrainment (Sedrakian and Shakhbasian, 1980; Alpar et al., 1984; Allard and Chamel, 2022), in analogy to the mixtures of liquid ^3He and ^4He (Andreiev and Bashkin, 1976), which implies that the motion of neutron fluid is accompanied by the motion of proton condensate and vice-versa. Mathematically, this arises from the off-diagonal elements of the matrix of densities which relates the fluid velocities to mass currents. As a result, the neutron circulation induces proton flow around the vortex, which in turn induces magnetization. Thus, neutron vortices acquire a non-quantized flux (Sedrakian and Shakhbasian, 1980; Alpar et al., 1984)

$$\phi^* = k_{\text{ent}} \phi_0, \quad k_{\text{ent}} = \frac{m_p^*}{m_p}, \quad (3)$$

where $\phi_0 = \pi/e$ is the flux quantum, while m_p^* and m_p are the effective and bare masses of protons.

An entrainment-like effect also takes place in the neutron star's inner crust consisting of neutron superfluid and plasma of crustal nuclei and electrons (Carter et al., 2006; Chamel, 2012, 2013, 2017; Watanabe and Pethick, 2017; Martin and Urban, 2016; Pethick et al., 2010; Kobayakov and Pethick, 2013). In this case also, the hydrodynamical mass current of each fluid is associated with the motion of the other. This has significant implications for the phenomenology of the neutron star glitches, through a reduction of the effective moment of inertia of the neutron superfluid, which rotates at a rate different from the crustal plasma that is locked to the rotation of the star.

Flux tubes and domains in the proton superconductor

Neutron stars are highly magnetized objects with typical field values in the range $B \sim 10^{12} - 10^{13}$ G. Along with the main population there are weak-field neutron stars, notably the millisecond pulsars with fields of the order $B \sim 10^8 - 10^9$ G and highly magnetized stars, known as magnetars, having $B \sim 10^{14} - 10^{15}$ G. Proton superconductors respond to this magnetic field depending on the local value of the Ginzburg-Landau parameter $\kappa_{\text{GL}} = \lambda^*/\xi_p$, where ξ_p is the proton coherence length and λ^* is the penetration depth of the magnetic field in superconductor.

In a wide range of densities in neutron star's core (and pasta phases of the inner crusts) one has $\kappa_{\text{GL}} > 1/\sqrt{2}$, indicating that the proton superconductor is type II. This implies that electromagnetic vortices are formed with a density (Sedrakian et al., 1995)

$$n_p^{(V)} = \frac{B}{\phi_0}, \quad \phi_0 = \frac{\pi}{e}, \quad (4)$$

where ϕ_0 is the flux quantum and B is the mean magnetic-field induction. As in metallic type II superconductors, the B -field will penetrate the proton superconductor if the field strength is between a lower critical field H_{c1} and an upper critical field H_{c2} . However, since neutron stars are expected to feature a magnetic field before proton superconductivity sets in and the timescales for the expulsion of the magnetic field from the star are very long, the flux remains frozen in the matter (Baym et al., 1969a). This implies that local regions of with high-intensity magnetic field can be formed with $H > H_{c1}$, which will allow quantum flux tubes to form. Computations show that in the high-density regime $\kappa_{\text{GL}} < 1/\sqrt{2}$, which implies a type I superconductivity (Bruk, 1973; Sedrakian et al., 1997; Wood and Graber, 2022). As known from condensed matter systems, flux tubes are unstable in this case. The field is then arranged in superconducting and normal domains. The size of the domains depends on the mesoscopic physics, but is expected to be significantly larger than the size of a flux tube, which is of the order of $\lambda^* \sim 100$ fm.

In magnetars the fields are so strong that their characteristic energy can be of the order of the gap. Indeed, we note that interior fields of magnetars could be of the order of $B \sim 10^{16} - 10^{17}$ G without affecting the hydrostatic stability of the star. The interaction between the nucleon spin and the magnetic field is given by the term $\mu_N B$, where $\mu_N = \hbar/2m_p$ is the nuclear magneton. Because this interaction will induce an imbalance in the numbers of spin-up and spin-down particles, one can anticipate that imbalance pairing patterns will arise in strongly magnetized superfluids in neutron stars. The fields at which the Chandrasekhar-Clogston limit is achieved are of the order $H_{c2} \sim 10^{16} - 10^{17}$ G for neutrons (Stein et al., 2016) and $H_{c2} \sim 10^{15}$ G for protons (Sinha and Sedrakian, 2015). Microscopic calculations show that the proton pairing gap and H_{c2} depend substantially on the density and it is plausible to expect that in some

regions of the star the condition $B \leq H_{c2}$ will be fulfilled, i.e., the superconductivity will be quenched by the field. It should be noted that the mechanism described above does not work in the case of spin-parallel P -wave pairing (Mizushima et al., 2021).

The protonic superconductor will form quantum vortex arrays which are much more dense than those in the neutron superfluid for typical fields of the order of 10^{12} G and typical rotation frequencies of neutron stars. The number of flux tubes per unit area of a single neutron vortex is of the order of 10^{13} . There exist several scenarios on how the networks of neutron and proton vortices interact, and evolve in time. The “frozen-in” scenario assumes that the proton vortex array is tightly bound to the global field of the star and neutron vortices move through pinning barriers formed by proton flux-tubes. This resistive flow would then determine the rate at which the superfluid will react to the changes in the rotational rate of the star. The problem is complicated by the fact that (a) the topology of the magnetic field could be quite complicated (e.g., poloidal, toroidal, etc. fields) and therefore the structure of the flux-tube networks may be intricate; (b) the force between neutron and proton vortices strongly depends on their relative orientation, therefore their coupled dynamics will depend on the assumed configurations.

As a consequence of the entrainment, a neutron vortex may carry a whole cluster of proton flux tubes colinear with it (Sedrakian et al., 1995). The reason is that in the vicinity of the core of the neutron vortex the field intensity is larger than H_{c1} (ignoring for the moment any “primordial” field), so the proton superconductor is inevitably forced to create flux tubes. A cluster “dressing” a neutron vortex provides a much more effective scattering target than a single neutron vortex magnetized by entrainment. This has interesting implications for the response time scales of the superfluid core to sudden glitches (Sedrakian and Cordes, 1999).

The interaction between neutron and proton components in the case of type-I superconductivity of protons is complicated due to a number of factors. In some cases, when simplifying assumptions about the structure of the domains are made, one can compute the dynamics of a neutron vortex embedded in a type-I superconductor. In this case the coupling of the superfluid to the normal matter turns out to be less efficient (Sedrakian, 2005).

Thermal evolution: Effects of superfluidity

The thermal evolution of neutron stars can be tentatively divided into three stages: (a) An initial fast transient of 100 years during which the star’s temperature drops to about 10^8 K at which the star’s core becomes isothermal. (b) The following $t \lesssim 10^5$ yr are characterized by neutrino emission from the star’s interior. This stage determines the subsequent evolution of the star and is important for interpretation of the X-ray data obtained from the observations by the satellites. (c) The last stage is characterized by the dominance of the photon emission from the surface of the star (Page et al., 2006).

The pairing of nucleonic components has significant effect on the cooling evolution of neutron stars and, therefore, the values of the gaps are crucial input in the simulations. Firstly, the pairing reduces the specific heat of nucleonic component in full analogy with the reduction of the specific heat of a superconductor as observed under terrestrial conditions. This reduces the “thermal inertia” of the star, which makes it easier to change its thermal content for a given energy loss mechanism. Secondly, because pairing blocks fermion excitations with energies smaller than twice the gap value, the neutrino radiation processes are exponentially suppressed for temperatures $T \ll \Delta$. This is quite analogous to the disappearance of resistivity in an ordinary superconductor due to the suppression of scattering by the gap. Thirdly, close to the critical temperature of pairing, close to which a star spends substantial time, pair-breaking and formation bremsstrahlung processes occur, in which Cooper pairs are thermally broken and recombined, with emission of neutrino-anti-neutrino pairs (Leinson and Pérez, 2006; Kolomeitsev and Voskresensky, 2008, 2010; Sedrakian, 2012). These processes are analogs of the condensed-matter processes of radio-frequency absorption by superconductors, which allow one to measure the magnitude of the gap in a variety of systems, including ultracold gases. Thus, one of the aims of research on thermal evolution of neutron stars is to place constraints on the pairing patterns and magnitudes of the gaps through a comparison of theoretical cooling curves with the observed surface temperature of neutron stars.

Selected key issues

Neutron gap, induced interactions, non-adiabatic effects

As should be clear from the discussion above, the magnitude of the pairing gap in neutron superfluid and proton superconductor is of crucial importance for modeling an array of problems in compact stars, including rotational dynamics (glitches, post-glitch relaxations), thermal evolution (specific heats, pair-breaking radiation rates), etc. While there is a convergence in the literature with regard to the mean-field and low-density behavior of the neutron gap, and some consensus about the suppression of the gap by the polarization effects, the ultimate role of various medium *effects* such as the polarization, off-shell contributions from the self-energy, and short-range correlations are still unsettled. Neutron pairing at subnuclear densities thus remains a topical issue where sophisticated many-body methods are called for. Non-adiabatic effects, well-known from the strong-coupling Eliashberg theories in condensed matter have rarely been considered in the case of nucleonic matter, but may offer an avenue to assess the impact of the induced interactions on the pairing gap beyond the Fermi-surface approximation.

The Proton gap and the role of the environment

The unbound proton component is commonly embedded in a much denser neutron component, whose effects on the proton pairing may be more significant than in the case of neutrons. For example, the polarization of the medium in this case and the contribution from the induced interaction may be larger than in the case of neutron matter. Short-range correlations and non-Fermi

liquid effects are expected to be more pronounced for protons, which fill a much smaller Fermi-sphere than neutrons. It is plausible that protons cannot be approximated, in a reasonable manner, as well-defined quasiparticles.

Higher-spin pairing

The P -wave superfluidity of neutrons at high densities is uncertain for several reasons. Firstly, the interactions are not fixed by phase-shifts above a certain density, so the results can vary widely. Secondly, the gap has many components characterized by various quantum numbers and, in addition, there is an important tensor coupling of the P to the F -wave. Thus, an accurate solution of the pairing problem even at the mean-field level poses a significant problem.

Superfluid fraction in neutron star crusts

The fraction of neutron superfluid in the crust can be reduced if some of it is entrained by the lattice component. The resulting reduction of the superfluid moment of inertia can be prohibitive for explanation of glitches by crust-based models only. There is an ongoing debate about the actual amount of entrained neutrons, the key issue being the inclusion of pairing effects in the band structure calculations (Watanabe and Pethick, 2017; Chamel, 2017; Kashiwaba and Nakatsukasa, 2019).

Conclusion

We have briefly reviewed some topics related to nucleonic superfluidity in neutron stars. It is evident that there are profound parallels to condensed matter systems, in particular to cold atomic gases where many features discussed can be studied experimentally under controlled conditions. At the same time, a closer look demonstrates that the physics of neutron stars requires answers to questions that have not been or in the future may not be in the focus of condensed matter theory.

At the microscopic scale, it can be stated that the pairing problem at the level of mean-field BCS theory, with the pairing interaction extracted directly from free-space nuclear interactions, is essentially solved within the density range corresponding to energies where the scattering phase shifts are known. Various microscopic many-body calculation predict pairing properties that vary to certain degree, specifically with regard to the issue of suppression of S -wave pairing in neutron matter by long-range collective fluctuations in the nuclear medium. Recent progress has been in the area of treating fluctuation corrections and the effects of short-range correlations due to the repulsion of the two-nucleon potential at short distances. The ultimate goal of achieving a convergent result at least in the low-density regime is within reach. More challenging problems include the studies of pairing at higher densities, in particular pairing gaps in the 3P_2 – 3F_2 channel, where the increasingly role of the three-nucleon forces cannot be neglected. Furthermore, the non-adiabatic effects (through the frequency dependence of the gap) and their impact on the phenomenology of neutron stars remains unexplored.

At meso-scales, it has been well established that the neutron superfluid rotates by forming a lattice of neutron vortices, protons are mostly type-II superconductors with characteristic critical fields within the range encountered in neutron stars, and pinning effects may play a prominent role both in the crust (vortex-nucleus pinning) and in the core (vortex-flux-tube) pinning. It has been shown that neutron vortices which are embedded in a proton superconductor acquire a non-quantized magnetic flux due to the entrainment effect; interestingly this observation does not have analogs in condensed matter theory to date. Open questions at the meso-scale involve (a) the structure of the pairing matrix for the 3P_2 – 3F_2 paired condensate and its vortex solutions, (b) type-I superconductivity in the deep core of a neutron stars, in its domain structure and dynamics, (c) the spatial form and structure of proton vortex flux tubes, their possible clustering, and their interaction with neutron vortices; (d) the mutual friction coefficients in each specific scenario of neutron pairing and type of superconductivity, (e) the amount of entrainment in the crust, which remains a significant problem for crust-only glitch models in spite of convergent results for pinning forces that have emerged in recent years.

At the macroscopic scales, modeling of neutron-star thermal evolution and dynamics and comparison with available and emerging data is needed to gain control over the physics at smaller scales. Open questions include the location of glitches (crust vs. core vs. mixed location models), the components of the star responsible for post-glitch relaxation, and understanding the diversity of post-glitch behavior in theoretical models. Accounting for the wide diversity of measured temperatures of neutron stars remains a challenge to theory, and the role played by pairing is far from being explored exhaustively, although our understanding of the basic process and their effects on cooling are solid.

In closing, we can be confident that a significant number of observational programs in the electromagnetic spectrum and in gravitational waves—those planned and those already operating—will provide the community with new information on neutron stars, which is so crucial for the feedback and development of the theory.

Abstract

The BCS-BEC crossover indicates the qualitative change in physical properties of Fermions with attractive interactions from the weakly to strongly interacting regime, offering an important guideline for maximizing T_c with given interactions. Though Uemura et al. (1991) pointed out that high- T_c cuprates and other exotic superconductors can be close to the crossover regime, the superconducting gap, Δ , is typically more than two orders of magnitude smaller than the Fermi energy, E_F . This suggests that these materials are still far from the crossover regime. Recently, several classes of new superconductors with comparable Δ and E_F have been discovered. Furthermore, the density-controlled BCS-BEC crossover has been achieved in gate-controlled two-dimensional superconductors. We review the recent progress of superconductor research from the viewpoint of the BCS-BEC crossover.

Key points

- With the development of experimental techniques, the BCS-BEC crossover has been investigated in several classes of new superconductors.
- Material research substantiated by theoretical approaches should be essential in exploring new physical properties in the BCS-BEC crossover.

Introduction

Fermions with attractive interactions, like electrons in a superconductor, show qualitatively different collective properties depending on the interaction strength. The BCS-BEC crossover indicates the change in physical properties from weak to strong interaction regions, and several classes of superconductors have recently been investigated in the context of the BCS-BEC crossover. In the Introduction, we review the concept of the BCS-BEC crossover, a short history on the experimental side, and a simple theoretical expectation. Then we move to the subsequent sections that focus on the recent material research.

We first explain the basic concept of the BCS-BEC crossover using Fig. 1 (Randeria and Taylor, 2014). For Fermions with weak attractive interactions (left side in Fig. 1), the formation and condensation of pairs with opposite spins occur at the same temperature ($T^* = T_c$), and superconductivity (or superfluidity for electrically neutral Fermions) appears below T_c . In such a weak-coupling region, which is known as the BCS regime, superconductivity can be described by the BCS theory. In contrast, in the strong-coupling region called the BEC regime (right side in Fig. 1), pair formation temperature T^* is much higher than condensation temperature T_c , and superconductivity is regarded as BEC of tightly bound pairs. The superconducting states in the BCS and BEC regimes are connected without any phase transition through a crossover, which is called the BCS-BEC crossover. Typically, the crossover appears around the unitarity, which is the threshold for the creation of a two-body bound state in the vacuum. Importantly, T_c could be maximized around the unitarity, and thus approaching from the BCS to the BEC regime possibly provides us with some hint toward room temperature superconductivity.

The history of research on the BCS-BEC crossover is rather old. Early on, researchers had superconductors (Eagles, 1969; Nozières and Schmitt-Rink, 1985) or liquid helium (Leggett, 1980) in mind, but since the BEC and BCS-BEC crossover were experimentally discovered in ultracold atoms of ^{40}K (Regal et al., 2004) and ^6Li (Zwierlein et al., 2004), the major target was changed to ultracold Fermion atoms. The biggest experimental advantage of ultracold atoms is that the interaction between two Fermions can be tuned

Fig. 1 Typical phase diagram for the BCS-BEC crossover (Randeria and Taylor, 2014). The horizontal axis represents the interaction strength measured by $1/k_F a$, where k_F and a are the Fermi wavenumber and s -wave scattering length, respectively. From Randeria M and Taylor E (2014) Crossover from Bardeen-Cooper-Schrieffer to Bose-Einstein condensation and the unitary Fermi gas. *Annual Review of Condensed Matter Physics* 5: 209.

by the application of an external magnetic field through the Feshbach resonance. This allows the ultracold atom systems to access the crossover regime from the BEC side. For example, recent experimental techniques have enabled direct measurements of the excitation spectrum of Fermions through the BCS-BEC crossover (Biss et al., 2022).

The BCS-BEC crossover was first discussed from the material viewpoint by Uemura et al. (1991). They found that many new superconductors discovered in the 1980s, including high- T_c cuprates, organics, heavy Fermions, and even fullerenes, have low carrier density and are positioned rather close to the BCS-BEC crossover regime with $k_B T_c / E_F \sim 0.05$, where E_F is the Fermi energy, as shown in the well-known Uemura plot. However, the superconducting temperatures of these superconductors do not reach the BEC temperature estimated from statistical mechanics, and reaching this BEC regime remained a challenge for the material science of superconductors in the last century.

In contrast to the ultracold atom experiments, systematic control of the Fermion interaction strength is usually difficult in experiments of superconductors. Instead, carrier density can be tuned by doping or in more sophisticated ways explained in the next section, and thus the carrier density-induced BCS-BEC crossover is the realistic target in superconductors in contrast to the case of ultracold atoms. Here we briefly discuss the importance of dimensionality in inducing the BCS-BEC crossover by the change in carrier density. In Fig. 2, we show the ground-state superconducting gap divided by the Fermi energy, Δ/E_F , as a function of the Fermion density, which is calculated by the mean-field theory for (Fig. 2A) two-dimensional (2D) and (Fig. 2B) three-dimensional (3D) Fermion gas models with contact attractive interactions. Here, we roughly regard the regions with $\Delta/E_F < 0.1$ and $\Delta/E_F > 1$ as the BCS and BEC regimes, respectively. For the 3D case (Fig. 2B), we show the curves for positive, negative, and zero inverse scattering lengths, corresponding to different interaction strengths. We can see the qualitative difference

Fig. 2 Ratio of the superconducting gap to the Fermi energy, Δ/E_F , as a function of density for the (A) 2D and (B) 3D Fermion gas models with contact attractive interactions, calculated by the mean-field theory. For (A), density is normalized by $mE_B/2\pi$, where m is the particle mass and E_B is the two-particle bound-state energy. For (B), a is the s -wave scattering length, where the unitarity corresponds to $a^{-1} = 0$; density is normalized by $|a|^{-3}$ and k_F^3 for $a^{-1} \neq 0$ and $a^{-1} = 0$, respectively, where k_F is the Fermi wavenumber.

between the 2D and 3D systems: reducing the density in the 2D system can induce the crossover from the BCS regime to the BEC regime, whereas the change of density in the 3D system can only achieve either the BCS or BEC side, depending on the interaction parameter a . This notable difference indicates that the unitarity limit (i.e., $a^{-1} = 0$) is moved to the BCS limit in the 2D case, suggesting that 2D systems have a great advantage for the experimental realization of the density-controlled BCS-BEC crossover in superconductors.

Density-controlled BCS-BEC crossover

Following the considerations above, it is natural for experimentalists to choose 2D or layered materials to realize the carrier density-induced BCS-BEC crossover in superconductors. The field effect transistor, or more broadly, the “gating” technique has been utilized in this direction since it is a powerful tool for controlling the carrier density in superconductors, especially in the low carrier density regime. Recently, the gate-controlled BCS-BEC crossover has been reported on two different materials. One is the twisted bi- or tri-layer graphene (Cao et al., 2018; Park et al., 2021), and the other is the Li-intercalated ZrNCl (Nakagawa et al., 2021; Heyl et al., 2022). The former graphene systems are well-known 2D superconductors, where superconductivity appears in the extremely low carrier density regime owing to its moire superlattice. The carrier density is continuously controlled by the gate voltage. The latter ZrNCl is a band insulator and a van der Waals layered material, which consists of double honeycomb ZrN layers sandwiched by Cl layers. Intercalated Li ions go into the van der Waals gap between the Cl layers and supply electrons to the ZrN layer, which leads to conducting and superconducting properties. The carrier density is changed through the amount of the Li ions, which were controlled by an ionic gating device with LiClO_4 /polyethylene glycol as an electrolyte.

Fig. 3 displays an electronic phase diagram for Li_xZrNCl . Here, Li amount x is supposed to be identical to the carrier density. In the high-density region, T_c is basically insensitive to the carrier density, whereas it forms a peak at $x \sim 0.01$. An important feature is that the pseudogap phase, detected by the tunneling spectroscopy, appears below $x = 0.1$, and its onset temperature T^* keeps increasing as x is decreased. The open triangles in Fig. 3 are the data obtained from the experiments on bulk polycrystalline samples, where $x = 0.05$ has been the limit (Kasahara et al., 2009). The ionic gating device has allowed us to go below this limit and reach the BCS-BEC crossover, as shown with the blue diamonds. Here we note that Li_xZrNCl is a layered material, and thus the system is highly two dimensional. Indeed, the resistive transitions exhibit the Berezinskii-Kosterlitz-Thouless (BKT) behavior with the BKT transition temperature T_{BKT} slightly lower than T_c . However, the difference between T_{BKT} and T_c is small and negligible in the scale of Fig. 3.

Fig. 4 is the so-called Uemura plot, which shows the relation between T_c and Fermi temperature T_F , as mentioned in the Introduction. The important feature of Li_xZrNCl is that it starts from the deep inside of the BCS regime and traverses all the way to the theoretical BEC line for 2D systems by reducing the carrier density by almost two orders of magnitude. When compared with the phase diagram in Fig. 3, one realizes that the region on the left side of the peak of T_c reaches the theoretical limit for 2D systems. This behavior is a clear demonstration of the density-induced BCS-BEC crossover.

Fig. 3 Electronic phase diagram of Li_xZrNCl (Nakagawa et al., 2021). Blue triangles show the superconducting transition temperature T_c defined by the half resistance. Red circles show the gap-opening temperature T^* from the tunneling spectroscopy.

Fig. 4 Uemura plot. The magenta and green dashed lines are the theoretical predictions for the BEC limits in 2D and 3D systems, respectively. Two plots designated by e and h for FeSe show the points for the electron and hole pockets, respectively. From Nakagawa Y, Kasahara Y, Nomoto T, Arita R, Nojima T, and Iwasa Y (2021) Gate-controlled BCS-BEC crossover in a two-dimensional superconductor. *Science* 372: 190.

Furthermore, comparing the experimental (Fig. 3) and theoretical (Fig. 1) phase diagrams, we find that these two show qualitatively the same behavior by appropriately exchanging the horizontal axis. The pseudogap phase disappears in the BCS regime of Fig. 3, whereas it rapidly grows as the carrier density is reduced. Presumably, the layered structure of Li_xZrNCl shifts the unitarity toward the BCS side and enables the density-controlled BCS-BEC crossover, just like the 2D case in Fig. 2A.

Uemura et al. (1991) pointed out that many exotic superconductors discovered in the 1980s and 1990s fell on the green belt in Fig. 4, but the value of T_c/T_F was still one order of magnitude smaller than the theoretical predictions for the BEC limit. However, new materials discovered in the past decades are indeed very close to the limit for 2D systems. In Fig. 4, we can find FeSe systems and twisted bilayer graphene. Interestingly, these are 2D or quasi-2D systems, but we should point out that the BCS-BEC crossover in 3D is not prohibited, but only the density-controlled crossover in purely 3D systems with fixed interaction strength is prohibited by the theory. In the following, we briefly address such newly emerging superconductors.

New materials

Graphene-based systems

The BCS-BEC crossover was first pointed out in the discovery paper of superconductivity in magic-angle twisted bilayer graphene (Cao et al., 2018). The twisted bilayer graphene is also a 2D system and the crossover was approached also by the gating technique, but in this case, by the standard solid gate dielectric of exfoliated hexagonal BN. Amazingly, superconductivity appeared at the extreme carrier density of $1.5 \times 10^{11} \text{ cm}^{-2}$ as optimal, which was determined by the quantum oscillation. This carrier density is more than two orders of magnitude smaller than the optimal value in Li_xZrNCl. They realized the value of $T_c/T_{\text{BEC}} = 0.37$, where the 3D value for the BEC limit ($T_{\text{BEC}} = 0.218T_F$) was used for comparison. This means that they have achieved $T_c/T_F = 0.08$, which is close enough to the BEC limit for 2D systems ($T_{\text{BEC}} = 0.125T_F$), as seen in Fig. 4. In Park et al. (2021), the same group reported that the twisted trilayer graphene also exhibits the BCS-BEC crossover and reaches $T_c/T_F = 0.125$, the limiting value for 2D systems.

Iron-based systems

Fig. 4 indicates that two groups of FeSe are placed near the 2D BEC line. One is the FeSe single crystal with $T_c = 9 \text{ K}$, and the other is the monolayer FeSe on the SrTiO₃ substrate. The former is a semimetal with a small carrier density, whereas, for the latter, many

electrons are doped possibly from the SrTiO_3 . Despite the big difference in T_c , which is around 9 K (Hsu et al., 2008) for the single crystal and 100 K for the monolayer (Ge et al., 2015), T_c/T_F is close to the 2D BEC limit of 0.125 for both systems. Since T_c in FeSe/ SrTiO_3 has not been reproduced since the first paper and remains controversial, we focus on the superconductivity of the FeSe single crystal in the following.

One of the distinctive features common in iron-based superconductors is the multiband electronic structure. In FeSe, the cylindrical hole and electron bands contribute to the Fermi surface and the low-energy excitations (Terashima et al., 2014). According to the ARPES and STS experiments (Kasahara et al., 2014; Hashimoto et al., 2020), the values of T_c/T_F are around 0.05 and 0.1 for the hole and electron bands, respectively, and $\Delta/E_F > 0.1$ for both the hole and electron bands, suggesting that FeSe undergoes superconductivity between the BCS and BEC regimes. Despite the large values of T_c/T_F and Δ/E_F , the pseudogap has not been observed in the STS measurements, which may be explained by the theoretically expected suppression of the pseudogap region due to the nature of compensated semimetal (Chubukov et al., 2016).

In the BCS-BEC crossover, since the pairing interaction energy becomes comparable to the kinetic energy, the effect of superconducting fluctuation is expected to be significant. In FeSe, enhancement of the diamagnetic susceptibility has been observed well above T_c (Kasahara et al., 2016). Fig. 5 shows the temperature dependence of the diamagnetic susceptibility in FeSe (light-blue and red points), compared with the prediction of the Gaussian fluctuation theory (blue line), which is applicable to superconductors in the BCS regime with small fluctuation effects. The large gap between the observed susceptibility and the theoretical prediction has been attributed to the enhanced superconducting fluctuation in the crossover regime, though a smaller fluctuation effect has also been reported on FeSe using a different measurement technique (Takahashi et al., 2019).

The multiband features in the BCS-BEC crossover have also been studied using the S-doped FeSe systems (Hashimoto et al., 2020). As the S doping is increased, the orthorhombic-tetragonal structural transition is known to occur, and the pseudogap has been observed in the tetragonal phase in ARPES experiments. In addition, the Bogoliubov quasiparticles show a relatively flat dispersion relation in the S-doped systems, which may be attributed to the interband coupling between multiple hole bands near the Γ point. A comprehensive understanding of the multiband effects in the BCS-BEC crossover will require further experimental and theoretical investigations.

Organic systems

Suzuki et al. (2022) announced the discovery of pressure-driven BCS-BEC crossover in an organic superconductor, $\kappa\text{-(BEDT-TTF)}_4\text{Hg}_{2.89}\text{Br}_8$ ($\kappa\text{-HgBr}$ hereafter). In this compound, dimers of BEDT-TTF molecules constitute a nearly isotropic triangular lattice, separated by insulating $\text{Hg}_{2.89}\text{Br}_8$ layers. The nonstoichiometry of Hg arises from its sublattice incommensurate with the host lattice formed by BEDT-TTF and Br. The triangular lattice structure is almost identical to that of the Mott-insulating spin liquid candidate $\kappa\text{-(BEDT-TTF)}_2\text{Cu}_2(\text{CN})_3$, in which the spin-1/2 localized on each BEDT-TTF dimer interacts with its neighbors through an antiferromagnetic exchange energy of 250 K but does not order down to 30 mK. Due to the nonstoichiometry in $\kappa\text{-HgBr}$, this compound is regarded as a hole-doped Mott insulator and exhibits superconductivity at $T_c \sim 5$ K under pressure above 0.24 GPa.

Fig. 5 Temperature dependence of the diamagnetic susceptibility above T_c (around 9K) for two values of the external magnetic field in FeSe (Kasahara et al., 2016). The vertical axis represents the difference between the ab -plane and c -axis susceptibilities with the subtraction of the corresponding value at a high field (7T). The blue line is the prediction of the Gaussian (Aslamasov-Larkin) fluctuation theory. T^* is the temperature at which the temperature derivative of resistivity takes the minimum, and the field dependence of the susceptibility is significant below T^* . From Kasahara S et al. (2016) Giant superconducting fluctuations in the compensated semimetal FeSe at the BCS-BEC crossover. *Nature Communications* 7: 12843.

Fig. 6 Pressure dependence of T_c and $k_F \xi_{||}$ for κ -(BEDT-TTF)₄Hg_{2.89}Br₈ (Suzuki et al., 2022). Regarding the points indicated by 80% and 90% in the $k_F \xi_{||}$ plot, $\xi_{||}$ is the coherence length derived from the out-of-plane upper critical field, which is defined by the magnetic field showing 80% and 90% of the normal-state resistivity, respectively. From Suzuki Y, Wakamatsu K, Ibuka J, Oike H, Fujii T, Miyagawa K, Taniguchi H, and Kanoda K (2022) Mott-driven BEC-BCS crossover in a doped spin liquid candidate kappa-(BEDT-TTF)₄Hg_{2.89}Br₈. *Physical Review X* 12: 011016.

Fig. 6 shows the pressure evolution of T_c and $k_F \xi_{||}$, where $\xi_{||}$ is the in-plane coherence length. $k_F \xi_{||}$ was estimated as 3 at low pressure, indicating that the material is already in the BCS-BEC crossover regime. As pressure is increased, $k_F \xi_{||}$ increases by a factor of 20 associated with the peaking of T_c , which indicates the crossover from the BEC to the BCS regime. According to the analysis, the pressure-induced change in $k_F \xi_{||}$ is dominated by the change in $\xi_{||}$, which indicates that the crossover is predominantly driven by the interaction strength. This poses an interesting contrast with the density-controlled BCS-BEC crossover in Li_xZrNCl and graphene systems.

Conclusion

In this chapter, we have reviewed recent studies on the BCS-BEC crossover in materials. According to a simple theory on Fermion gas systems, 2D materials are expected to have the advantage of realizing the BCS-BEC crossover by tuning the carrier density. Indeed, the density-controlled crossover has been found in 2D-like ZrNCl and graphene-based systems using the gating technique. More broadly, several kinds of materials have been reported as candidates in the crossover or even BEC regime. From the viewpoint of the BCS-BEC crossover, we have explained the essential features of graphene-based, iron-based, and organic systems. Material research supported by theoretical approaches will be crucial in elucidating the guiding principles for realizing the BCS-BEC crossover and exploring new physical properties.

Abstract

There is accumulating evidence for the existence of quantum condensation of excitons in double layer semiconductor heterostructure devices, with the electrons and holes spatially separated in adjacent parallel conducting layers. This has sparked a lot of interest in excitonic superfluidity at equilibrium. The electron-hole pairing attraction is strong, promising high transition temperatures. Because the attraction is long-ranged, screening controls many superfluid properties. The systems offer the exciting prospect of a tunable electronic device that can sweep across the superfluid BCS-BEC crossover regimes. Pros and cons of different candidate heterostructures are discussed, accompanied by a brief overview of the current experimental status.

Key points

- How to generate equilibrium excitonic superfluidity and Bose Einstein condensation
- Systems are double conducting-layer semiconductor electronic devices
- Electrons and holes are separated in adjacent layers to avoid recombination
- Electron-hole pairing attraction is strong
- Pairing attraction is long-ranged so screening controls many superfluid properties
- Systems can be tuned across all the superfluid BCS-BEC crossover regimes
- Advantages and disadvantages of different material configurations
- Current experimental status

Introduction

The electrons and holes in semiconductors can form bound pairs called excitons. The attraction between the charged electrons and holes is Coulombic, with strong exciton binding energies that can exceed thermal energies even at room temperature.

In the phenomenon of conventional superconductivity, weakly bound pairs of electrons quantum condense into a single quantum state. This allows the condensate to flow through the metallic conductor without resistance. The electron pairs are bound by a residual attraction that is weak, so the dissipation-less flow of electrical current is generally limited to very low temperatures.

Based on the strong electron-hole Coulomb attraction, [Keldysh and Kopayev \(1965\)](#) predicted many years ago that, not only should excitons quantum condense, but the energy gap of the resulting superfluid should be large. However, realization of superfluidity was blocked by the very short exciton lifetimes, as the electrons and holes recombine and destroy the exciton. The short lifetimes make it difficult for the excitons to quantum condense in bulk semiconductors. One workaround is to couple the excitons to light confined in a cavity. Hybrid exciton-polaritons can be formed with long enough lifetimes to quantum condense ([Kasprzak et al., 2006](#)). However, to maintain a constant exciton-polariton population it must be optically pumped, leading to a non-equilibrium steady-state. [Lozovik and Yudson \(1975, 1976\)](#) and [Shevchenko \(1976\)](#) proposed instead to generate equilibrium electron-hole superfluidity by separating the electrons and holes in a semiconductor heterostructure, confining them in two adjacent quantum wells. This suppresses electron-hole recombination and stabilizes the exciton lifetimes indefinitely. This article focuses on realizations of this idea.

Implementation of the idea remained technically unfeasible for many years. The quantum well subbands form quasi two-dimensional conducting layers with typical average interparticle spacings $r_0 \sim 10$ nm. To generate a population of excitons with strong electron-hole attraction and weak screening, the quantum wells must be fabricated no more than a perpendicular distance r_0 apart ([Neilson et al., 1993](#); [Liu et al., 1996, 1998](#)). This is no mean task.

When the layer separation is less than the effective Bohr radius typical of semiconductors, the exciton binding energies can approach ~ 1000 K, leading to large superfluid energy gaps, ~ 300 K ([Perali et al., 2013](#)). However in two-dimensional systems, large superfluid gaps do not in general translate into high transition temperatures. The reason is that strong fluctuations, together with the topological nature of the two-dimensional Berezinskii-Kosterlitz-Thouless transition ([Berezinsky, 1972](#); [Kosterlitz and Thouless, 1973](#)), make the transition temperature only dependent on the density. The transition temperature does not depend on the strength of the pairing interaction.

A further major challenge in electron-hole superfluidity is screening of the long range pairing attraction. We recall that most superconductors and superfluids involve contact or short-range pairing interactions, so screening is not important. With the pair interaction for electron-hole superfluidity that is Coulombic and long-range, screening effects are unavoidable and strong. In fact, screening can weaken the pairing attraction to such a degree that superfluidity would occur only at impractically low temperatures ([Kharitonov and Efetov, 2008](#)). However at low enough densities, the existence of a large superfluid gap in the excitation energy spectrum can block low-lying single-particle excitations near the Fermi surface sufficiently to allow strong-coupled superfluidity ([Lozovik et al., 2012](#); [Perali et al., 2013](#)). But even when strong-coupled superfluidity does stabilize, the maximum transition temperature is in general capped at low values. This is because of the joint effect of the transition temperature being determined by the density and the superfluidity being restricted to low densities.

Theory of electron-hole superfluidity

The electron-hole bilayer system consists of an n -doped and a p -doped conducting layer separated by a thin insulating layer of thickness d and dielectric constant κ ([Fig. 1](#)). V^{eh} is the electron-hole attractive screened interaction between the layers, and $V^{ee}(V^{hh})$ are the repulsive Coulomb interactions for the electrons (holes) interacting within their layers. Voltages applied to the top and bottom metal gates, V_{TG} and V_{BG} , and a voltage across the layers, $V_{BB'}$, are used to adjust the electron and hole densities n ([Lee et al., 2014](#); [Zeng and MacDonald, 2020](#)). Changing the densities, changes the average strength of the electron-electron (hole-hole) Coulomb interactions, $\langle V^{ee}(V^{hh}) \rangle = e^2/\kappa r_0 = e^2\sqrt{\pi n}/\kappa$. The most favorable condition for superfluidity is an equilibrium exciton gas with equal electron and hole densities ([Pieri et al., 2007](#)).

Fig. 1 Schematic representation of double electron-hole layer system. An upper conducting layer of electrons and a lower conducting layer of holes are separated a distance d by a thin insulating layer. Average interparticle spacing within each layer is r_0 . The interactions are electron-hole between the layers, V^{eh} , and electron-electron (hole-hole) within the layers, V^{ee} (V^{hh}). The potentials V_{TG} and V_{BT} are from top and bottom metal gates which, together with the bias between the layers V_{BB} , tune the electron and hole densities.

Superfluid equations

At zero temperature, a BCS mean-field description is a good approximation for strong-coupling superfluidity as well as for the familiar weak-coupling case (Nozières and Pistolesi, 1999). For the p-doped bilayer, the standard particle-hole transformation is used to map the negative-energy valence band to a positive-energy conduction band, with positively charged holes filling their conduction band states up to a Fermi level $E_F > 0$.

The BCS normal Green function $\mathcal{G}(\mathbf{k}, i\varepsilon_n)$ and anomalous Green function $\mathcal{F}(\mathbf{k}, i\varepsilon_n)$ for symmetric electron and hole bands with dispersion $\varepsilon_{\mathbf{k}}$ are given by (Lozovik and Sokolik, 2010),

$$\begin{aligned}\mathcal{G}(\mathbf{k}, i\varepsilon_n) &= \frac{u_{\mathbf{k}}^2}{i\varepsilon_n - E_{\mathbf{k}}} + \frac{v_{\mathbf{k}}^2}{i\varepsilon_n + E_{\mathbf{k}}} \\ \mathcal{F}(\mathbf{k}, i\varepsilon_n) &= \frac{u_{\mathbf{k}}v_{\mathbf{k}}}{i\varepsilon_n - E_{\mathbf{k}}} - \frac{u_{\mathbf{k}}v_{\mathbf{k}}}{i\varepsilon_n + E_{\mathbf{k}}},\end{aligned}\quad (1)$$

with energies $E_{\mathbf{k}} = \sqrt{\xi_{\mathbf{k}}^2 + \Delta_{\mathbf{k}}^2}$, $\xi_{\mathbf{k}} = \varepsilon_{\mathbf{k}} - \mu$, and Bogoliubov factors, $v_{\mathbf{k}} = \sqrt{\frac{1}{2}(1 - \xi_{\mathbf{k}}/E_{\mathbf{k}})}$ and $u_{\mathbf{k}} = \sqrt{\frac{1}{2}(1 + \xi_{\mathbf{k}}/E_{\mathbf{k}})}$. For a given value of the chemical potential in the superfluid, $\mu \leq E_F$, the equations for the momentum-dependent electron-hole superfluid energy gap $\Delta_{\mathbf{k}}$ and density n are,

$$\Delta_{\mathbf{k}} = -\sum_{\mathbf{k}'} \frac{1}{2} \mathcal{F}_{\mathbf{k}-\mathbf{k}'}^{eh} V_{\mathbf{k}-\mathbf{k}'}^{eh} \frac{\Delta_{\mathbf{k}'}}{2E_{\mathbf{k}'}}, \quad n = 2g_v \sum_{\mathbf{k}} v_{\mathbf{k}}^2. \quad (2)$$

$V_{\mathbf{k}-\mathbf{k}'}^{eh}$ is a screened interaction between the electrons and holes that depends on the momentum exchange in the scattering process. This gives the superfluid gap its momentum dependence. The form factor $\mathcal{F}_{\mathbf{k}-\mathbf{k}'}^{eh}$ accounts for the overlap between the electron and hole single-particle wave functions. g_v is the valley degeneracy.

There have been extensions of the mean-field approach to non-symmetric electron and hole bands and to unequal densities (Pieri et al., 2007; Subasi et al., 2010; Conti et al., 2021a).

Screening in a superfluid

When there is a superfluid energy gap, the screened interaction $V_{\mathbf{k}-\mathbf{k}'}^{eh}$ in Eq. (2) must be determined self-consistently. In the static limit, it is given by the linear-response expression (Lozovik and Sokolik, 2010),

$$V_{\mathbf{q}}^{eh} = \frac{V_0^{eh}(\mathbf{q})}{1 - 2V_0^{ee}(\mathbf{q})\Pi_0(\mathbf{q}) + \left[(V_0^{ee}(\mathbf{q}))^2 - (V_0^{eh}(\mathbf{q}))^2 \right] (\Pi_0(\mathbf{q}))^2} \quad (3)$$

where $V_0^{eh}(\mathbf{q}) = -2\pi e^2 e^{-qd}/(\kappa q)$ is the bare electron-hole Coulomb attraction, and $V_0^{ee}(\mathbf{q}) (V_0^{hh}(\mathbf{q})) = 2\pi e^2/(\kappa q)$ the bare electron-electron (hole-hole) Coulomb repulsion within a layer. For Fermi liquids the linear-response polarizability $\Pi_0(\mathbf{q})$ is the static Lindhard function for a two-dimensional layer (Stem, 1967), but in a superfluid, $\Pi_0(\mathbf{q}) = \Pi_0^{(n)}(\mathbf{q}) + \Pi_0^{(a)}(\mathbf{q})$, a sum of the normal (n) and anomalous (a) linear response polarizabilities (Lozovik et al., 2012; Perali et al., 2013).

The polarizabilities $\Pi_0^{(n)}(\mathbf{q})$ and $\Pi_0^{(a)}(\mathbf{q})$ for the superfluid are constructed from the normal and anomalous Green functions (Fig. 2). Summing the fermionic Matsubara frequencies ε_n of the particle-hole loop, and taking the static limit (Lozovik et al., 2012),

$$\Pi_0^{(n)}(\mathbf{q}) = -2g_v \sum_{\mathbf{k}} \mathcal{F}_{\mathbf{q}}^{ee} \frac{u_{\mathbf{k}}^2 v_{\mathbf{k}-\mathbf{q}}^2 + v_{\mathbf{k}}^2 u_{\mathbf{k}-\mathbf{q}}^2}{E_{\mathbf{k}} + E_{\mathbf{k}-\mathbf{q}}} \quad (4)$$

$$\Pi_0^{(a)}(\mathbf{q}) = 2g_v \sum_{\mathbf{k}} \mathcal{F}_{\mathbf{q}}^{eh} \frac{2u_{\mathbf{k}}v_{\mathbf{k}}u_{\mathbf{k}-\mathbf{q}}v_{\mathbf{k}-\mathbf{q}}}{E_{\mathbf{k}} + E_{\mathbf{k}-\mathbf{q}}}. \quad (5)$$

$\mathcal{F}_{\mathbf{q}}^{ee}$ is the electron-electron form factor.

Fig. 2 Normal and anomalous polarizabilities $\Pi_0^{(n)}(q)$ and $\Pi_0^{(a)}(q)$ made up of two normal and two anomalous Green functions, respectively.

$\Pi_0^{(n)}(q)$ and $\Pi_0^{(a)}(q)$ in the superfluid state are suppressed for small momentum transfers q for two reasons. The presence of a superfluid gap in the excitation energy spectrum increases the magnitude of the energy denominators in the polarizabilities, which weakens the screening. In addition, for any non-zero energy gap, there is an exact cancellation of the sum $\Pi_0^{(n)}(q) + \Pi_0^{(a)}(q)$ at $q = 0$, rigorously eliminating screening in the long-wave limit (Lozovik et al., 2012). Increasing the strength of the superfluid gap expands the range of q over which the screening is suppressed. When $\Delta \gg E_F$, screening in the superfluid state is completely suppressed by Δ . The physical picture is that, with such strong coupling, the electron-hole pairs are compact relative to their spacing, quasi-neutral excitons which mutually interact through weak dipole repulsion. Since the pairs closely resemble weakly interacting bosons, screening is negligible (Perali et al., 2013).

Nilsson and Aryasetiawan (2021) have extended the self-consistent approach to include dynamic screening (see also Sodemann et al., 2012). Intralayer interaction contributions to the quasiparticle self-energies, and hence to E_k , have been considered by Debnath et al. (2017). These generalizations introduce corrections that renormalize the coupling strength and the superfluid gap.

Superfluid crossover physics

Eagles (1969), Leggett (1980), and Nozières and Schmitt-Rink (1985) developed a formalism for the BCS–BEC crossover, in which the spontaneous symmetry broken Bardeen–Cooper–Schrieffer (BCS) (Bardeen et al., 1957) superfluidity smoothly connects with Bose–Einstein condensation (BEC) (Schafroth et al., 1957) through a continuous reduction in the spatial size of the fermion pairs, here electron-hole pairs. As the pair coupling interaction is strengthened, the electron-hole pairs evolve from weakly-coupled, diffuse, interpenetrating Cooper pairs, the BCS regime, to pairs comparable in diameter to their spacing in the layers, the BCS-BEC crossover regime, and finally to pairs that are compact, non-overlapping composite bosons, the BEC regime. For a review, see Strinati et al. (2018).

An important feature of a semiconductor bilayer heterostructure is that the average coupling strength $\langle V^{ee} \rangle / E_F$ can be tuned by changing the density. In the example of parabolic bands, the Fermi energy $E_F \sim 1/r_0^2$, so $\langle V^{ee} \rangle / E_F \sim r_0$. Thus the electron-hole layers can be swept continuously across the BCS-BEC crossover regimes of the superfluid, starting from the weak coupled BCS regime at high densities (small r_0) to the strong-coupled BEC regime at low densities (large r_0) (Pieri et al., 2007; Perali et al., 2013; Liu et al., 2022).

The nature of the superfluidity in each of the regimes can be characterized by the dependence on k of the superfluid gap Δ_k . These properties are illustrated in Fig. 3, showing Δ_k in the three BCS to BEC crossover regimes. The regimes have been identified independently using the superfluid condensate fraction CF (Guidini and Perali, 2014). For the weak-coupled BCS limit, corresponding to $CF \leq 0.2$, the $\Delta_k \ll E_F$ is narrowly peaked at $k = k_F$, reflecting the interpenetrating nature of the Cooper pairs.

Fig. 3 Contrasting momentum dependence of the superfluid gap Δ_k for the different BCS-BEC crossover regimes as labeled, with the corresponding value of the condensate fraction CF. Δ_k is scaled with the Fermi energy E_F , k with the Fermi momentum k_F .

Fig. 4 Superfluid gap $\Delta_{\max}$, the maximum of Δ_k in effective Rydbergs Ry^* as a function of the average interparticle distance r_0 . a_B^* is the effective Bohr radius. The curves compare the mean-field results for self-consistent static screening (MF-SCSS), for self-consistent dynamic screening (MF-SCDS), and in the absence of screening (MF-US). With self-consistent screening, there is a superfluid onset density (small arrows) at which $\Delta_{\max}$ drops by orders of magnitude.

In the BCS-BEC crossover regime, $0.2 < CF < 0.8$, the maximum in Δ_k is of the order of E_F and has shifted to $k < k_F$, with a broad peak. In the BEC regime, $CF \geq 0.8$, the maximum is at $k = 0$, and $\Delta_k \gg E_F$ is almost constant out to $k \gg k_F$, corresponding to pairs that are compact in real space compared with the interparticle spacing.

Superfluid gap and superfluid onset density

Fig. 4 demonstrates a central rôle played by screening for the long-range pair interaction. The system is double bilayer graphene with a 1 nm thick hexagonal boron nitride insulating barrier. $\Delta_{\max}$ is the maximum of Δ_k . In the weak-coupled regime at high densities, small r_0 , the value of $\Delta_{\max}$ calculated without screening (MF-US) is much larger than $\Delta_{\max}$ calculated with self-consistent screening, both static (MF-SCSS) and dynamic (MF-SCDS). While this difference is to be expected, the figure reveals a striking additional result: in the presence of screening there exists a superfluid onset density n_0 , above which there is a sharp orders of magnitude decrease in $\Delta_{\max}$. For densities $n > n_0$, the superfluidity is negligible, with the superfluid gap lying in the mKelvin energy range (Kharitonov and Efetov, 2008). In real systems, residual disorder would more than likely destroy such weakly bound pairs.

While screening is responsible for completely suppressing superfluidity at high densities, by contrast in the strong-coupled region at low densities, $r_0/a_B^* > 4$, it is the superfluidity that suppresses the effect of screening. In this case, $\Delta_{\max}$ calculated with or without screening is the same. This occurs because $\Delta_{\max} \gg E_F$, blocking the low-lying states that are responsible for screening.

Fig. 4 also shows the effect of dynamics on the screening (Nilsson and Aryasetiawan, 2021). At low densities, screening is unimportant. However, at higher densities the magnitude of the superfluid gap is increased by the dynamic corrections to static screening and the onset density is higher.

The results shown in Figs. 3 and 4 were determined within the mean-field approximation with self-consistent screening. Effects such as self-energy insertions, vertex corrections, etc., are not considered. For this reason, it is useful to compare these results with results determined from a full diffusion quantum Monte-Carlo calculation which includes all these additional effects. Fig. 5 compares results calculated using diffusion quantum Monte-Carlo (López Ríos et al., 2018), with a mean-field calculation for the same system using the static self-consistent screened pairing interaction (Neilson et al., 2014). The system is the same as for Fig. 4.

Fig. 5(a) shows that the superfluid gap $\Delta_{\max}$ from mean-field with self-consistent screening is substantially in agreement with the full quantum Monte Carlo result. This demonstrates that the mean-field calculation with self-consistent screening captures the essence of the phenomenon, including the remarkable existence and the location of an onset density.

Fig. 5(b) characterizes the BCS-BEC crossover regimes, comparing the diffusion quantum Monte-Carlo superfluid condensate fraction CF with the condensate fraction from mean-field. In most of what should be the BCS regime, the density is already above the onset density, so in most of the BCS regime the weak superfluidity cannot overcome the strong screening (Perali et al., 2013).

Superfluid transition temperature

The binding energies of the pairs in these double layer systems can be very large, resulting in large superfluid gaps $\Delta_{\max} > 300$ K, but disappointingly, these huge values do not usually translate into room temperature superfluidity. This is because in two-dimensional systems, transition temperatures are tightly capped by the Mermin-Wagner theorem (Mermin and Wagner, 1966; Hohenberg, 1967). The maximum transition temperature is limited by the topological properties of the Berezinskii-Kosterlitz-Thouless (BKT) transition (Kosterlitz and Thouless, 1973). The transition temperature T_c^{BKT} is, up to a constant, equal to the superfluid stiffness $\rho_s(T)$. It depends only on the density and it is not affected by the coupling strength. For parabolic bands, it is linearly proportional to the density, $T_c^{BKT} = \left[\frac{\pi}{2} \frac{\hbar^2}{2M} \right] n$, where M is the mass of the electron-hole pair. Consequently, the maximum transition temperature $T_c^{\max}$ occurs at the superfluid onset density, $n = n_0$.

Fig. 5 Comparison of (a) superfluid gap $\Delta_{\max}$ in effective Rydbergs Ry^* and (b) superfluid condensate fraction CF, calculated within mean-field using self-consistent static screening (MF-SCSS) and by a full diffusion quantum Monte Carlo (QMC) calculation. r_0/a_B^* is the average interparticle distance scaled with the effective Bohr radius. In (b) the BCS-BEC crossover regimes are indicated on the right axis.

The complete phase diagram is shown in Fig. 6. Above the onset density $n > n_0$, the superfluid transition temperature is in the mKelvin range, above which the system is a Fermi liquid. For $n < n_0$ and temperatures above T_c^{BKT} , signatures of the superfluid state should persist arising from the pseudogap. The pseudogap arises from localized dynamic fluctuations of the pairing field (Franz, 2007), and is a precursor of the superfluid gap in the normal degenerate electron gas. It extends up to the degeneracy temperature T_D (Butov, 2004). As it can be significant up to temperatures $T \sim \Delta_{\max}$ (Perali et al., 2002; Gaebler et al., 2010), in the present case the pseudogap could survive to room temperature.

Identifying superfluidity

To identify clear signatures of electron-hole superfluidity remains a major challenge. Although the superfluid current is neutral, nevertheless because the charged electrons and holes are spatially separated, an electrical current can be generated by passing counterflow currents in the two layers in opposite directions (Sivan et al., 1992; Su and MacDonald, 2008). Since in a superfluid

Fig. 6 Temperature-density T - n phase diagram. T_c^{BKT} is the superfluid transition temperature. n is the equal density of electrons and holes. The maximum transition temperature $T_c^{\max}$ occurs at the onset density n_0 . For densities $n > n_0$, the superfluid transition temperature is in the mKelvin range. T_D is the degeneracy temperature for the exciton gas.

the counter-currents will couple to the dissipationless neutral exciton current, the counter-currents are expected also to be dissipationless (Eisenstein and MacDonald, 2004; Fil and Shevchenko, 2018).

Properties of the electron-hole drag resistance, the bilayer transresistivity, is another signature of condensation (Conti et al., 1998; Hu, 2000). The transresistivity is directly related to the interlayer scattering rate (Narozhny and Levchenko, 2016), and using a minimum dissipation principle for the superfluid current, Vignale and MacDonald (1996) showed that superfluidity can be characterized by a discontinuous jump in the drag resistance at the transition temperature. As the temperature is further decreased, the drag resistance diverges for temperatures approaching zero.

Enhanced electron-hole tunneling between the layers is a further indicator of spontaneous interlayer phase coherence (Eisenstein and MacDonald, 2004; Efimkin et al., 2020). However, Zeng and MacDonald (2020) showed that a strong interlayer tunneling current between the layers influences the transport and can lead to a steady state that is not in equilibrium.

Josephson junction-like behavior across a weak link could also be used in identifying superfluidity (Zenker et al., 2015; Pascucci et al., 2022).

Systems

Although the electron-hole double layer system is a multiband system, with a hole band and an electron band, it is possible to have just a single condensate with the one gap parameter. This is diametrically opposite to multiband superconductors like magnesium diboride in which the pairing occurs within the bands and for which multiple coupled condensates must appear, each condensate with a gap parameter associated with a different band (Komendová et al., 2012).

Gallium arsenide double quantum wells

Electron-hole superfluidity and BCS-BEC crossover physics was first proposed for an excitonic system in a conventional semiconductor heterostructure of double quantum wells in gallium arsenide (Comte and Nozières, 1982). Technical advances in the early 1990s in the fabrication of double quantum wells in III-V semiconductors offered an apparently unobstructed path (Balatsky et al., 2004) to experimentally realize superfluidity in a double layer semiconductor system (Sivan et al., 1992; Kane et al., 1994; Pohl et al., 2002). Charge-separated excitons were produced by confining electrons and holes in adjacent quantum wells consisting of two disconnected thin slabs of gallium arsenide, with a very thin slab of aluminum gallium arsenide between them as an insulating barrier (Butov et al., 2002).

Superfluidity in gallium arsenide double quantum wells differs in important ways from superfluidity in coupled atomically flat layers like graphene (Section “Double monolayer graphene”). Advantages include a large bandgap, and low-energy bands that are insensitive to gate potentials. Pieri et al. (2007) showed that the large difference in the electron and hole effective masses in gallium arsenide, $m_h^*/m_e^* \sim 5$, as well as any density imbalance, have further intriguing consequences. The large mass difference should lead to the existence of the exotic superfluid phases, Fulde-Ferrel-Larkin-Ovchinnikov (FFLO) (Fulde and Ferrell, 1964; Larkin and Ovchinnikov, 1965) and Sarma (Sarma, 1963).

However, a significant drawback of gallium arsenide is that in double quantum wells, the electron-hole pairing interactions are weak since it is difficult to fabricate the wells sufficiently close to each other. A limitation with transport in quantum wells is that the wells must not be fabricated too narrow (<12 nm for gallium arsenide), otherwise interface roughness scattering increases rapidly when the well is made narrower, resulting in samples with very low mobilities. This restriction places tight limits on minimum effective electron-hole separations (Saber-Pouya et al., 2020), and the formation of excitons is exponentially suppressed when the thickness of the insulating barrier exceeds the effective Bohr radius, $a_B^* = 13$ nm in gallium arsenide.

Bose-Einstein condensation of excitons has been reported in gallium arsenide double quantum wells using optical pumping (Butov, 2004; High et al., 2012). Because of the fast recombination of the photoexcited excitons, the condensate was not in equilibrium.

With transport measurements, there have been independent reported observations at low temperature of strong nonmonotonic deviations of the Coulomb drag on the hole layer away from the $\sim T^2$ behavior expected for a Fermi-liquid (Croxall et al., 2008; Seamons et al., 2009; Das Gupta et al., 2011). However no clear, consistent signature has emerged that the deviations are associated with a superfluid transition. This is consistent with theoretical predictions. For the smallest quantum well separations fabricated to date, the pairing interactions are still too weak and the lowest densities currently attained remain a little above the predicted superfluid onset density (Saber-Pouya et al., 2020). At such low densities, charge-carrier freeze-out occurs and the conducting layers become insulators. Disconnected puddles of superfluidity might survive, randomly distributed along the quantum well interfaces. These could be detected using capacitance spectroscopy.

Double monolayer graphene

The fabrication of graphene atomic monolayers (Novoselov et al., 2004) opened up new possibilities by replacing the finite width quantum wells of the III-V semiconductors with atomically-thin layers of graphene. The discovery of the extraordinarily efficient insulating properties of hexagonal boron nitride (Britnell et al., 2012), reduced separations between the layers to unprecedentedly

small values (Min et al., 2008; Lozovik and Sokolik, 2008). A hexagonal boron nitride barrier has a much larger bandgap, ~ 5 eV, than the gallium aluminum arsenide barrier in gallium arsenide double quantum wells (~ 0.5 eV), and just three monolayers of hexagonal boron nitride, of total thickness 1 nm between two monolayers of graphene are sufficient to eliminate the electron-hole tunneling current between the layers. Such a barrier is thin on the scale of the effective Bohr radius in graphene ($a_B^* \sim 10$ nm).

Because the energy bands in monolayer graphene are symmetric and have zero bandgap, the Dirac cone, the superfluidity would be inherently multicomponent with intraband pairing of electrons and holes that come from the same band, as well as crosspairing between the conduction and valence bands (Shanenko et al., 2012). The mean-field formalism for electron-hole superfluidity was generalized to multicomponents by Lozovik and Sokolik (2010).

Unfortunately however, since the energy bands follow a linear dispersion, $\varepsilon(k) = \pm \hbar v_F k$, with v_F the constant Fermi velocity, the kinetic energy decreases linearly with the inter-particle spacing r_0 , making $\langle V \rangle / E_F$, the ratio of the average Coulomb energy to Fermi energy, independent of density. Lozovik et al. (2012) showed that only when $\langle V \rangle / E_F > 2.35$ is the pair coupling strong enough for a superfluid gap to suppress the screening, allowing the superfluidity to exist. For the band parameters in graphene, $\langle V \rangle / E_F \sim 0.7$, so the pair coupling strength would always be too weak. Thus at any density in monolayer graphene, superfluidity is suppressed by screening. Because the electrons and holes are massless, localized excitons cannot form (Lozovik and Sokolik, 2008). If any remnant superfluidity survived in the presence of such strong screening, its transition temperature T_c would be impractically low (Kharitonov and Efetov, 2008). Lozovik and Sokolik (2010) and Sodemann et al. (2012) generalized the static screening theory to dynamic screening. Dynamic screening did not alter the key conclusion that superfluidity is not to be expected in double monolayer graphene.

Electron-hole Coulomb drag measurements of Gorbachev et al. (2012) bear this conclusion out. No jump or divergence in the drag resistance was observed, and the T^2 temperature behavior of the drag resistance across the full density and temperature range was consistent with Fermi liquid properties.

Double bilayer graphene

With the difficulties faced by double monolayer graphene, Perali et al. (2013) proposed an alternate strategy: to substitute two graphene bilayers for the two graphene monolayers while retaining the hexagonal boron nitride insulating barrier. In graphene bilayers, the energy bands $\varepsilon(k)$ resemble the bands of conventional semiconductors and are approximately parabolic. Then, as in the semiconductors, reducing the density increases $\langle V \rangle / E_F$ and strengthens the pair coupling.

With strong electron-hole coupling, the superfluidity can overcome the screening. The suppression of screening is more dramatic for the quadratic bands of bilayer graphene than for linear bands of monolayer graphene. This is because with the larger density of states for quadratic bands, the corresponding gaps from Eq. (2) are larger, while at the same time E_F is smaller. A larger Δ / E_F ratio is more effective at suppressing the screening.

The bandgap for bilayer graphene is very small and tunable, typically $E_g \sim 5 - 100$ meV, up to a maximum $E_g \sim 250$ meV. The bandgap is determined by the gate voltages. For such small bandgaps, the valence band provides a second superfluid gap, and the superfluid is multicomponent.

The two superfluid components are coupled through Josephson-like transfers of electron-hole pairs between the valence and conduction band condensates (Conti et al., 2017). This should reinforce the superfluid gaps, but with small bandgaps there are additional interband contributions to the screening coming from valence to conduction band excitations (Conti et al., 2019). These two effects act in opposing directions. In the end, the effect of the additional screening that weakens the superfluid gaps turns out to be the stronger effect, making Josephson-like transfers negligible (Conti et al., 2019). The reason is the following. These transfers would leave in their trail a population of free vacancies in the valence-band, adding to the screening. This makes the resulting superfluid gaps always smaller than the bandgap, so Josephson-like pair transfers are suppressed. Without the pair transfer, the net result is that the conduction and valence band condensates are decoupled, with the conduction band condensate dominant. For small bandgaps, the conduction band condensate is weakened by the additional interband screening arising from single-particle excitations out of the valence band. As the bandgaps get bigger, interband screening weakens and the conduction band superfluid gap becomes stronger.

A further advantage of large bandgaps comes from the fact that the bilayer graphene conduction band is flatter than a parabolic band for low energies (Castro et al., 2010). This results in a larger density of states, so the Fermi energy E_F at a given density is reduced, thus permitting a superfluid gap of a given magnitude to block a wider range of low-lying excitations. This more efficiently suppresses the screening, and the superfluid gap is increased.

In summary, in double bilayer graphene the superfluid onset density is sensitive to the variable bandgap. When the bandgap $E_g < E_F$, the interband contributions reinforce the screening, and the onset density is low. Conversely, when $E_g \gg E_F$ the onset density is larger. For a separation between the bilayers $d = 1$ nm and bandgap $E_g \gtrsim 35$ meV, the onset density $n_0 \gtrsim 2 \times 10^{11} \text{ cm}^{-2}$. This puts strong-coupled superfluidity in the BCS-BEC crossover and BEC regimes within experimental reach in double bilayer graphene.

Burg et al. (2018) observed strongly enhanced interlayer tunneling at equal electron and hole densities in double bilayer graphene separated by a $d = 1.4$ nm tungsten diselenide insulating barrier. Below a temperature $T_c \sim 1.5$ K, the interlayer tunneling current had a vertical onset as a function of interlayer voltage, suggesting a transition to a coherent state at that temperature. Such tunneling enhancement is a strong indicator of exciton condensation. The interlayer current I_{int} was measured as a function of the interlayer voltage V_{BB} , at fixed top and back gate voltages, V_{TG} and V_{BG} (see Fig. 1).

The vertical onset of the interlayer tunneling current and the tunneling enhancement were observed at densities only below an onset density $n_0 = 8 \times 10^{11} \text{ cm}^{-2}$, a value consistent with theory (Perali et al., 2013; López Ríos et al., 2018; Nilsson and Aryasetiawan, 2021).

Double transition metal dichalcogenide monolayers

To circumvent the detrimental effect of the valence band screening encountered in double bilayer graphene, Conti et al. (2020b) suggested double monolayers from the transition metal dichalcogenide (TMD) family, specifically, molybdenum disulfide, molybdenum diselenide, tungsten disulfide, and tungsten diselenide. This group have large bandgaps, $E_g \gtrsim 1 \text{ eV}$ (Mak et al., 2010; Jiang, 2012).

The conduction bands in this class of transition metal dichalcogenides are split by spin-orbit coupling, leading to two condensates in the conduction bands and hence multicomponent superfluidity. The two superfluid components reinforce the superfluidity in this case (Conti et al., 2017). In addition, the electron and hole effective masses are large, increasing the binding energies compared to bilayer graphene. This further strengthens the electron-hole pairing interactions (Fogler et al., 2014). Lagoin and Dubin (2021) pointed out that the presence of moiré potentials in transition metal dichalcogenides heterobilayers will further enhance the effective masses.

As a result of the large bandgaps, the reinforcing multicomponent effects, and the large effective masses, the superfluid onset densities in double layer transition metal dichalcogenides are high, with a 1 nm barrier, $n_0 \sim 1 \times 10^{13} \text{ cm}^{-2}$ (Conti et al., 2020b). These are much larger than in double bilayer graphene, $n_0 \sim 8 \times 10^{11} \text{ cm}^{-2}$ (Burg et al., 2018; Conti et al., 2019), phosphorene, $n_0 \sim 4 \times 10^{12} \text{ cm}^{-2}$ (Saber-Pouya et al., 2018), and gallium arsenide, $n_0 \sim 5 \times 10^{10} \text{ cm}^{-2}$ (Saber-Pouya et al., 2020). With such high onset densities, the transition metal dichalcogenides hold great promise for exciton superfluids at high-temperature, with transition temperatures predicted as high as $T_c^{BKT} \sim 100 \text{ K}$ (Conti et al., 2020b).

This family of materials hosts additional curious possibilities. Conti et al. (2020a) showed that by exploiting a change in the energy band alignments, certain combinations of transition metal dichalcogenides can provide a doping-dependent switch, to switch from one-component to two-component superfluidity (Conti et al., 2020b). The switch in doping also affects the spin alignment of the electron-hole pairs, leading to an intriguing possibility of tuning from a system purely of dark excitons to a system purely of bright excitons (Combescot et al., 2017).

Enhanced interlayer tunneling and enhanced electroluminescence intensity have been observed in molybdenum diselenide–tungsten diselenide separated by 1–2 nm of hexagonal boron nitride (Wang et al., 2019; Chaves and Neilson, 2019; Ma et al., 2021). Again there was an onset density, below which a large tunneling current was observed between the monolayers. At exactly equal electron–hole densities, the electroluminescence intensity from electron–hole recombination triggered by inter-layer tunneling was strongly enhanced, a property again consistent with exciton condensation. The tunneling enhancement and the electroluminescence intensity shared the same onset density, and the properties persisted up to remarkably high temperatures, $T_c \sim 100 \text{ K}$ (Fogler et al., 2014).

Indium arsenide–gallium antimonide double quantum wells

Indium arsenide–gallium antimonide double quantum wells have an inverted band structure with finite overlap of the conduction and valence bands. With electrons in the indium arsenide well and holes in the gallium antimonide well, the electrons and holes are in equilibrium without photoexcitation, and they are spatially separated without the need for a barrier.

Du et al. (2017) reported optical spectroscopic and electronic transport evidence for the formation of an excitonic insulator gap in this system at relatively high densities. Terahertz transmission spectra exhibited two absorption lines which are quantitatively consistent with predictions from the pair-breaking excitation dispersion, calculated based on the BCS superfluid gap equation (Eq. 2). Transport measurements show an insulating gap of $\Delta \sim 25 \text{ K}$, with a transition temperature of $T_c \sim 10 \text{ K}$ which, with quantized edge conductance, suggests the existence of a topological excitonic insulator phase.

Future systems

Other quantum wells

Silicon-germanium double quantum wells

Conti et al. (2021b) have proposed electron-hole quantum wells in a strained silicon-germanium double layer heterostructure as an interesting alternative system for superfluidity. Because of the Type-II band alignment of the silicon-germanium interface (Virgilio and Grosso, 2006), there is no requirement for an insulating barrier to keep the electrons and holes apart, as is needed in gallium arsenide double quantum wells. The resultant close proximity of the electrons and holes greatly enhances the electron-hole pair interaction, leading to much higher onset densities than in gallium arsenide. A compressively strained 3 nm epitaxial germanium layer and tensile strained 3 nm epitaxial silicon layer ensures that the layers are lattice matched. The low-lying bands result in a double quantum well structure, with the electrons confined in the silicon well and the holes in the germanium well. In the presence of the strain, the effective mass imbalance is large, $m_h^*/m_e^* = 0.26$ (Lodari et al., 2021; Schäffler, 1997; Zwanenburg et al., 2013).

The system offers some unique advantages. One is the ability to independently contact the layers since there exists no quantum well for holes in the silicon layer and there is no quantum well for electrons in the germanium layer that is energetically accessible. This makes it straightforward with a simple and robust process, to independently electrically contact just one layer and not the other. In contrast, to fabricate independent contacts for the systems already discussed requires painstaking multi-stage processing.

A second distinct advantage is scalability. The silicon-germanium heterostructures would be grown on 300 mm silicon wafers using mainstream chemical vapor deposition (Pillarisetty, 2011). In this way, these heterostructures can take advantage of state-of-the-art semiconductor manufacturing, promising high device yield and integration. A silicon-germanium bilayer is readily integrated with advanced quantum technologies (Scappucci et al., 2020), including long-lived electron spin qubits in silicon (Watson et al., 2018), hole spin qubit arrays in germanium (Hendrickx et al., 2020), and superconducting contacts to holes (Vigneau et al., 2019).

By contrast, device fabrication for double graphene bilayers and double transition metal dichalcogenide bilayers involves layer by layer assembly using pick and transfer techniques. These are prone to layer wrinkling, contamination, and misorientation (Frisenda et al., 2018). Device yields tend to be low and prospects for scalability limited. III-V semiconductor based devices such as gallium arsenide, offer more promise for scalability, but the molecular beam epitaxy growth technique is not compatible with standard complementary metal-oxide semiconductor technology, thus limiting the prospects for advanced manufacturing and large scale device integration.

Other atomically thin layers

Double monolayer graphene in a periodic magnetic field

To boost the value of the ratio $\langle V \rangle / E_F$, Dell'Anna et al. (2015) proposed applying a periodically modulated external magnetic field perpendicular to the two graphene monolayers. The magnetic field preserves the linear dispersion of the graphene monolayer energy bands, but it reduces the constant Fermi velocity v_F , flattening the gradient of the bands. This reduces E_F , increases $\langle V \rangle / E_F$, and strengthens the superfluid pair coupling. A magnetic field $B_\perp \gtrsim 1$ T with a periodicity $\lesssim 10$ nm, would boost $\langle V \rangle / E_F$ above 2.35 (see Section "Double monolayer graphene"). The resulting superfluid gaps are large, of the order of hundreds of Kelvin.

There is an upper limit $B_\perp^{\max}$ on the magnetic field strength. At $B_\perp^{\max}$, the Fermi energy passes through the top of the band of the magnetic field. Once the Fermi energy is in the bandgap, the assumption that the spectrum is linear is no longer valid.

Nanoribbons from double monolayer graphene

Zarenia et al. (2016) predicted strong electron-hole superfluidity in coupled monolayer graphene armchair-edge terminated nanoribbons, separated by a hexagonal boron nitride insulating barrier (Fig. 7). The nanoribbons would be independently contacted, with top and bottom metal gates to tune the densities.

In contrast to graphene monolayers, the bands of the nanoribbons are parabolic at low energies and there is a bandgap. As a result, the screening of the electron-hole pairing interaction is much weaker compared with coupled graphene monolayers. The one-dimensional quantum confinement of the electrons and holes further enhances the pairing attraction. The one-dimensional van Hove enhancement of the density of states magnifies superfluid shape resonances from the confinement (see (Perali et al., 1996; Bianconi et al., 1997, 1998)), acting non-linearly through the superfluid gap equation to enhance the magnitude of the gaps. The resulting superfluidity is strong-coupled with very large superfluid gaps that can be in excess of $\Delta \sim 1000$ K. The superfluidity is multicomponent, with different condensates for the multiple subbands of the nanoribbon.

Hybridization of double bilayer graphene

In double bilayer graphene with separations between the bilayers less than $d = 1$ nm, the electron-hole pairing interaction would become very strong, potentially increasing superfluid onset densities and hence transition temperatures. However, for separations $d < 1$ nm, electron-hole recombination rates will be extremely rapid, thus making equilibration uncertain. When the separation

Fig. 7 Electron-doped and hole-doped armchair-edge terminated graphene nanoribbons of width W separated by a hexagonal boron nitride insulator (h-BN) of thickness d . Top and back metal gates tune the densities.

between the graphene bilayers is comparable to the thickness of each bilayer (0.37 nm (Nilsson et al., 2008)), strong hybridization will occur across all four monolayers making up the double graphene bilayer system. Su and MacDonald (2017) demonstrated that there could exist a rich diagram of novel phases, including spin-density-wave states and mixed excitonic and spin order states. In practice, with tunneling rates that grow exponentially as the bilayer separations decrease, whether these new phases could be realized is unclear.

Double trilayer and quadlayer graphene

Zarenia et al. (2014) extended the idea of increasing the density of states, and thus reducing the Fermi energy for a given density, to double trilayer and double quadlayer graphene. The additional layers depress the Fermi energy at a given density, which further strengthens the coupling in the superfluid. The strong coupling increases the onset density and hence the maximum transition temperature. For double quadlayer graphene, transition temperatures as high as $T_c^{BKT} \sim 40$ K are predicted.

Double van der Waals layers with Type-III interfaces

Gupta et al. (2020) identified lattice-matched van der Waals double monolayer heterostructures with broken-gap Type-III interface band alignment, in which the top of the valence band in the upper layer lies above the bottom of the conduction band in the lower layer. This band alignment permits electrons to spontaneously transfer from the top of the upper-layer valence band to the bottom of the lower-layer conduction band, leaving a hole behind in the upper-layer valence band. In this way, the Type-III interface spontaneously generates without gate voltages, spatially separated densities of electrons and holes that are in equilibrium. As with Type-II interfaces, Type-III interfaces need no insulating barrier to separate the electrons and holes, leading to strong electron-hole pairing interactions. The density range, $10^{11} - 10^{13} \text{ cm}^{-2}$, is experimentally accessible. To sweep across the different BCS-BEC crossover regimes, the densities can be tuned with gate voltages or with strain.

Superlattice of transition metal dichalcogenide monolayers

Van der Donck et al. (2020) proposed overcoming the topological limitations on the Berezinskii-Kosterlitz-Thouless transition temperature, by replacing the double electron-hole layers with a superlattice of alternating electron-doped and hole-doped layers. Since a superlattice is a three-dimensional structure, the transition is no longer topological, opening a new way for the strong electron-hole pairing interactions and the correspondingly large superfluid gaps to be exploited, so as to drive the transition to much higher temperatures. A superlattice of alternating tungsten disulfide and tungsten diselenide monolayers, was demonstrated to be optimal, with transition temperatures close to room temperature, $T_c \sim 270$ K.

Conclusion

This chapter has presented an overview to a phenomenon that recently has received impetus from accumulating experimental evidence that equilibrium electron-hole superfluidity, encompassing Bose-Einstein condensation of excitons and BCS-BEC crossover physics, is realizable in semiconductor heterostructure devices in which electrons and holes are kept spatially separated in adjacent parallel conducting layers. The electron-hole pairing attraction is strong, promising high transition temperatures. Because the attraction is long-ranged, screening determines many superfluid properties. Heterostructures currently receiving much attention include gallium arsenide and indium arsenide–gallium antimonide double quantum wells, and graphene and transition metal dichalcogenide double layers. Advantages, disadvantages, and the current experimental status of these and other promising systems have been discussed. To identify clear signatures of electron-hole superfluidity remains a major challenge. Current efforts focus on searching for dissipationless counterflow currents in the two layers, electron-hole drag resistance, and enhanced electron-hole tunneling between the layers combined with electroluminescence from the ensuing recombination. An ability to investigate crossover physics in electronic devices at equilibrium offers exciting prospects for the future.

Acknowledgments

I am grateful to Dr. Sara Conti for a great deal of assistance in the preparation of this article.

Abstract

The phenomenon of superfluidity (superconductivity) is a possibility of transport of mass (charge) on macroscopical distances without essential dissipation. In magnetically ordered media with easy-plane topology of the order parameter space the superfluid transport of spin is also possible despite the absence of the strict conservation law for spin. The article addresses three key issues in the theory of spin superfluidity: topology of the order parameter space, Landau criterion for superfluidity, and decay of superfluid currents via phase slip events, in which magnetic vortices cross current streamlines. Experiments on detection of spin superfluidity are also surveyed.

Key points

- Spin superfluidity is the possibility to transport spin with essentially suppressed dissipation on long distances.
- Spin superfluidity is possible if the magnetic order parameter space has the topology of a circumference.
- The necessary topology is provided by easy-plane anisotropy in ferromagnets or by magnetic field in antiferromagnets.
- Metastability of spin superfluid current states is restricted by the Landau criterion.
- Decay of spin superfluid currents is realized via phase slips, in which magnetic vortices cross current streamlines.

Introduction

The phenomenon of superfluidity (superconductivity in the case of charged fluids) is known more than a hundred years. Its analog for spin (spin superfluidity) occupies minds of condensed matter physicists from 70s of the last century. The term *superfluidity* is used in the literature to cover a broad range of phenomena in superfluid ^4He and ^3He , Bose-Einstein condensates of cold atoms, and solids. In this article superfluidity means only the possibility to transport a physical quantity (mass, charge, spin, ...) without dissipation (more accurately, with essentially suppressed dissipation). This corresponds to the original hundred-years old meaning of the term from the times of Kamerlingh Onnes and Kapitza.

The superfluidity is conditioned by the special topology of the order parameter space (vacuum manifold). Namely, this topology is that of a circumference in a plane. The angle of rotation around this circumference is the order parameter phase describing all degenerate ground states. In superfluids the phase is the phase of the macroscopic wave function. In magnetically ordered systems (ferro- and antiferromagnets) the necessary topology is provided by easy-plane magnetic anisotropy, and the phase is the angle of rotation around the axis (further the axis z) normal to the easy plane. Currents of mass (charge) or spin are proportional to phase gradients and are called supercurrents.

In early discussions of the spin supercurrent it was considered as a counterflow of superfluid currents of particles with different spins in superfluid ^3He (Vuorio, 1974), i.e., spin was transported by itinerant spin carriers. Later it was demonstrated that spin superfluidity is a universal phenomenon, which does not require mobile spin carriers and is possible in magnetic insulators (Sonin, 1978a, 1982). It can be described within the framework of the standard Landau–Lifshitz–Gilbert (LLG) theory. However, the publications conditioning spin superfluid transport by the presence of mobile carriers of spin continued to appear in the literature (Bunkov, 1995; Shi et al., 2006). According to Shi et al. (2006), it is a critical flaw of spin-current definition if it predicts spin currents in insulators.

Strictly speaking the analogy of spin superfluidity with superfluids is complete only if there is invariance with respect to any rotation in the spin space around the axis z . Then according to Noether's theorem the spin component along the axis z is conserved.

But there is always some magnetic anisotropy, which breaks the rotational invariance. Correspondingly, there is no strict conservation law for spin, while in superfluids the gauge invariance is exact, and the conservation law of mass (charge) is also exact.

In the past there were arguments about whether superfluidity is possible in the absence of the conservation law. This dispute started at discussion of superfluidity of electron-hole pairs or excitons. The number of electron-hole pairs can vary due to interband transitions, and the degeneracy with respect to the phase of the pair condensate is lifted. Guseinov and Keldysh (1972) called this effect “fixation of phase.” They demonstrated that spatially *homogeneous* stationary current states are impossible, and concluded that there is no analogy with superfluidity. However, later it was demonstrated that phase fixation does not rule out the existence of weakly *inhomogeneous* stationary current states analogous to superfluid current states (Kulik and Shevchenko, 1976; Lozovik and Yudson, 1977; Sonin, 1977). This analysis was extended on spin superfluidity (Sonin, 1978a,b, 1982). In magnetism violation of the spin conservation law usually is rather weak because it is related with relativistically small (inversely proportional to the speed of light) processes of spin-orbit interaction. In fact, the LLG theory itself is based on the assumption of weak spin-orbit interaction (Landau and Lifshitz, 1980).

Above we discussed supercurrents generated in the equilibrium (ground state) of the magnetically ordered medium with easy plane topology. But in magnetically ordered system this topology is possible also in non-equilibrium coherent precession states, when spin pumping supports spin precession with fixed spin component along the magnetic field. Such non-equilibrium coherent precession states, which are called nowadays magnon BEC, were experimentally investigated in the *B* phase of superfluid ^3He and in yttrium-iron-garnet (YIG) films (Bunkov, 1995; Demokritov et al., 2006).

Spin superfluid transport is possible as long as the spin phase gradient does not exceeds the critical value determined by the Landau criterion. The Landau criterion checks stability of supercurrent states with respect to elementary excitations of all collective modes. The Landau criterion determines a threshold for the current state instability, but it tells nothing about how the instability develops. The decay of the supercurrent is possible only via phase slips. In a phase slip event a magnetic vortex crosses current streamlines decreasing the phase difference along streamlines. Below the critical value of supercurrent phase slips are suppressed by energetic barriers. The critical value of the supercurrent at which barriers vanish is of the same order as that estimated from the Landau criterion. This leads to a conclusion that the instability predicted by the Landau criterion is a precursor of the avalanche of phase slips not suppressed by any activation barrier.

The superfluid spin transport on macroscopical distances is possible only if the spin phase performs a large number of full 2π rotations along current streamlines (large winding number), and phase slips are suppressed by energetic barriers. On the other hand, small phase variations less than 2π are ubiquitous in magnetism. They emerge in any spin wave, any domain wall, or due to disorder. Their existence is confirmed by numerous experiments in the past. Spin currents generated by these small phase differences transport spin only on small distances and oscillate in space or time, or both. Their existence is not a manifestation of spin superfluidity.

In last decades the interest to spin superfluidity was revived (Bunkov and Volovik, 2013; Chen and MacDonald, 2017; Evers and Nowak, 2020; Iacocca et al., 2017; Qaiumzadeh et al., 2017; Sonin, 2010, 2017, 2019b, 2020; Sun et al., 2016; Takei et al., 2014; Takei and Tserkovnyak, 2014; Tserkovnyak and Kläui, 2017) in connection with the emergence of spintronics. The present article reviews the three essentials of the spin superfluidity concept: topology, Landau criterion, and phase slips. The article focuses on the qualitative analysis avoiding details of calculations, which can be found in original papers. After the theoretical analysis the experiments searching for spin superfluidity are shortly discussed.

Concept of superfluidity

Let us remind the concept of superfluidity for the transport of mass (charge). In superfluid hydrodynamics there are the Hamilton equations for the pair of the canonically conjugate variables “phase-particle density”:

$$\hbar \frac{d\varphi}{dt} = -\frac{\delta\mathcal{H}}{\delta n}, \quad \frac{dn}{dt} = \frac{\delta\mathcal{H}}{\hbar\delta\varphi}. \quad (1)$$

Here

$$\frac{\delta\mathcal{H}}{\delta n} = \frac{\partial\mathcal{H}}{\partial n} - \nabla \cdot \frac{\partial\mathcal{H}}{\partial \nabla n}, \quad \frac{\delta\mathcal{H}}{\delta\varphi} = \frac{\partial\mathcal{H}}{\partial\varphi} - \nabla \cdot \frac{\partial\mathcal{H}}{\partial \nabla\varphi} \quad (2)$$

are functional derivatives of the Hamiltonian

$$\mathcal{H} = \frac{\hbar^2 n}{2m} \nabla\varphi^2 + E_0(n), \quad (3)$$

φ is the phase of the wave function describing the Bose-Einstein condensate (BEC) in Bose liquids or the Cooper pair condensate in Fermi liquids, and $E_0(n)$ is the energy of the superfluid at rest, which depends only on the particle density n . Taking into account the gauge invariance [$U(1)$ symmetry] $\partial\mathcal{H}/\partial\varphi = 0$, the Hamilton equations are reduced to the equations of hydrodynamics for an ideal liquid:

$$m \frac{dv}{dt} = -\nabla \mu, \quad (4)$$

$$\frac{dn}{dt} = -\nabla \cdot \mathbf{j}. \quad (5)$$

In these expressions

$$\mu = \frac{\partial E_0}{\partial n} + \frac{\hbar^2}{2m} \nabla \varphi^2 \quad (6)$$

is the chemical potential, and

$$\mathbf{j} = n\mathbf{v} = \frac{\partial \mathcal{H}}{\partial \nabla \varphi} \quad (7)$$

is the particle current. We consider the zero-temperature limit, when the superfluid velocity coincides with the center-of-mass velocity of the whole liquid:

$$\mathbf{v} = \frac{\hbar}{m} \nabla \varphi. \quad (8)$$

The continuity equation Eq. (5) satisfies the conservation law of mass (charge), which follows from the gauge invariance.

A collective mode of the ideal liquid is a plane sound wave $\propto e^{i\mathbf{k}\cdot\mathbf{r}-i\omega t}$ with the wave vector $\mathbf{k}$, the frequency ω , and the linear spectrum $\omega = u_s k$. The sound velocity is

$$u_s = \sqrt{\frac{n}{m} \frac{\partial^2 E_0}{\partial n^2}}. \quad (9)$$

In the sound wave the phase varies in space, i.e., the wave is accompanied by mass currents [Fig. 1(a)]. An amplitude of the phase variation is small, and currents transport mass on distances of the order of the wavelength. A real superfluid transport on macroscopic distances is possible in current states, which are stationary solutions of the hydrodynamic equations with finite constant currents, i.e., with constant nonzero phase gradients. In the current state the phase rotates through a large number of full 2π -rotations along streamlines of the current [Fig. 1(b)]. These are supercurrents or persistent currents.

The crucial point of the superfluidity theory is why the supercurrent in Fig. 1(b) is a metastable state and does not decay a long time. The first explanation of the supercurrent metastability was the well known Landau criterion (Landau, 1941). According to this criterion, the current state is stable as far as *any quasiparticle* in a moving liquid has a positive energy in the laboratory frame and therefore its creation requires an energy input. Let us suppose that elementary quasiparticles of the liquid at rest have an energy $\varepsilon(\mathbf{p}) = \hbar\omega(\mathbf{k})$, where $\mathbf{p} = \hbar\mathbf{k}$ is the quasiparticle momentum. If the liquid moves with the velocity $\mathbf{v}$ the quasiparticle energy in the laboratory frame becomes $\tilde{\varepsilon}(\mathbf{p}) = \varepsilon(\mathbf{p}) + \mathbf{p}\cdot\mathbf{v}$. This is the Doppler effect in the Galilean invariant fluid. The current state is stable if the energy $\tilde{\varepsilon}$ is never negative. This condition is the Landau criterion:

Fig. 1 Phase (in-plane rotation angle) variation in space at the presence of mass (spin) currents. (a) Oscillating currents in a sound (spin) wave. (b) Stationary mass (spin) supercurrent. From Sonin EB (2010) Spin currents and spin superfluidity. *Advances in Physics* 59: 181–255.

$$v < v_L = \min \frac{\varepsilon(\mathbf{p})}{p} = \min \frac{\omega(\mathbf{k})}{k}. \quad (10)$$

If quasiparticles are phonons (quanta of sound waves) the Landau critical velocity v_L is the sound velocity u_s . In superfluid ^4He the Landau critical velocity v_L is determined by the roton part of the spectrum. It is a few times less than the sound velocity.

The Landau criterion checks the stability with respect to elementary microscopic perturbations of the current state, but does not provide an information how the instability would develop. The whole process of the supercurrent decay is connected with generation of macroscopic perturbations. These perturbations are quantum vortices. If the vortex axis (vortex line) coincides with the z axis, the phase gradient around the vortex line is given by

$$\mathbf{v}_v = \frac{\hbar}{m} \nabla \varphi_v = \frac{\kappa [\hat{z} \times \mathbf{r}]}{2\pi r^2}, \quad (11)$$

where $\mathbf{r}$ is the position vector in the xy plane and $\kappa = h/m$ is the velocity circulation quantum.

Creation of the vortex requires some energy. The vortex energy per unit length (line tension) is determined mostly by the kinetic (gradient) energy in the area not very close to the vortex axis where the particle density does not differ essentially from its equilibrium value n_0 (the London region):

$$\varepsilon_v = n_0 \int d^2 \mathbf{r} \frac{\hbar^2 (\nabla \varphi_v)^2}{2m} = \frac{\pi \hbar^2 n_0}{m} \ln \frac{r_m}{r_c}. \quad (12)$$

The upper cut-off r_m of the logarithm is determined by geometry. For the vortex shown in Fig. 2(a) it is the distance of the vortex line from a sample border. The lower cut-off r_c is the vortex-core radius. It determines the distance r at which the phase gradient is so high that the density n starts to decrease compared to the equilibrium density n_0 at large r . The energy $E_0(n)$ of the resting superfluid at small $n - n_0$ is determined by the fluid compressibility:

$$E_0(n) = E_0(n_0) + \frac{m(n_0 - n)^2 u_s^2}{2n_0}. \quad (13)$$

At the distance r_c from the vortex axis the energy $m n \nabla \varphi_v^2 / 2$ becomes of the order of the compressibility energy at $n_0 - n \sim n_0$. This happens when the velocity $v_v(r)$ induced by the vortex becomes of the order of the sound velocity u_s . This yields $r_c \sim \kappa / u_s$. Inside the core the density vanishes at the vortex axis eliminating the singularity in the kinetic energy. For the weakly non-ideal Bose-gas r_c is on the order of the coherence length.

Phase slips are impeded by energy barriers determined by topology of the order parameter space (vacuum manifold). The order parameter of a superfluid is a complex wave function $\psi = \psi_0 e^{i\varphi}$, where the modulus ψ_0 of the wave function is a positive constant determined by minimization of the energy and the phase φ is a degeneracy parameter. Any degenerate ground state in a closed annular channel (torus) with some constant phase φ maps on some point at the circumference $|\psi| = \psi_0$ in the complex plane ψ , while a current state with the phase change $2\pi N$ around the torus maps onto a path [Fig. 3(a)] winding around the circumference N times. The integer winding number N is a topological charge. The current can relax if it is possible to change the topological charge.

Fig. 2 Mass and magnetic vortices. (a) Vortex in a superfluid or magnetic vortex in an easy-plane ferromagnet without in-plane anisotropy. (b) magnetic vortex at small average spin currents ($\langle \nabla \varphi \rangle \ll 1/l$) for fourfold inplane symmetry. The vortex line is a confluence of four 90° domain walls (solid lines). From Sonin EB (2010) Spin currents and spin superfluidity. *Advances in Physics* 59: 181–255.

Fig. 3 Topology of the uniform mass current and the vortex states. (a) The current state in a torus maps onto the circumference $|\psi| = \psi_0$ in the complex ψ -plane, where ψ_0 is the modulus of the equilibrium order parameter wave function in the uniform state. (b) The current state with a vortex maps onto the circle $|\psi| \leq \psi_0$. From Sonin EB (2010) Spin currents and spin superfluidity. *Advances in Physics* 59: 181–255.

A change of the topological charge from N to $N - 1$ is possible, if a vortex generated at one border of a channel with a moving superfluid moves across current streamlines “cutting” the channel cross-section, and annihilates at another border as shown in Fig. 2 (a). This is a phase slip. In the phase slip event the distance r_m of the vortex from a border varies from zero to the width W of the channel. The energy of the vortex in a moving superfluid is determined by a sum of the constant gradient $\nabla\varphi_0$, which determines the supercurrent, and the phase gradient $\nabla\varphi_v$ induced by the vortex. The vortex energy consists of the energy of the vortex in a resting fluid given by Eq. (12) and of the energy from the cross terms of the two gradient fields $\nabla\varphi_0$ and $\nabla\varphi_v$:

$$\tilde{e}_v = \frac{\pi\hbar^2 n_0}{m} L \ln \frac{r_m}{r_c} - \frac{2\pi\hbar^2 n_0}{m} S \nabla\varphi_0, \quad (14)$$

where L is the length of the vortex line and S is the area of the cut, at which the phase jumps by 2π . For the 2D case shown in Fig. 2 (a) (a straight vortex in a slab of thickness L normal to the picture plane) $S = Lr_m$. The vortex motion across the channel (growth of r_m) is impeded by the barrier determined by the maximum of the energy $\tilde{e}_v$ as a function r_m . The height of the barrier is the vortex energy at $r_m = 1/2 \nabla\varphi_0$:

$$e_b \approx \frac{\pi\hbar^2 n}{m} L \ln \frac{2}{r_c \nabla\varphi_0}. \quad (15)$$

The barrier disappears at gradients $\nabla\varphi_0 \sim 1/r_c$, which are of the same order as the critical gradient determined from the Landau criterion. On the other hand, in the limit of small velocity $v \propto \nabla\varphi_0$ the barrier height grows and at very small velocity $v \sim \hbar/mW$ reaches the value

$$e_m \approx \frac{\pi\hbar^2 n}{m} L \ln \frac{W}{r_c}. \quad (16)$$

Thus, in the thermodynamic (macroscopic) limit $W \rightarrow \infty$ the barrier height becomes infinite. Since the phase slip probability exponentially decreases on the barrier height (whether the barrier is overcome due to thermal fluctuations or via quantum tunneling) the life time of the current state in conventional superfluidity diverges when the velocity (phase gradient) decreases. This justifies calling superfluidity macroscopic quantum phenomenon.

In the 3D geometry the phase slip is realized with expansion of vortex rings. For the ring of radius R the vortex-length and the area of the cut are $L = 2\pi R$ and $S = \pi R^2$ respectively, and the barrier disappears at the same critical gradient $\sim 1/r_c$ as in the 2D case.

The state with the vortex in a moving superfluid maps on the full circle $|\psi| \leq \psi_0$ [Fig. 3(b)]. The area outside the vortex core maps on the circumference $|\psi| = \psi_0$, while the core maps on the interior of the circle. In a weakly interacting Bose-gas the structure of the core is determined by solution of the Gross—Pitaevskii equation (Pitaevskii and Stringari, 2003; Sonin, 2016). The details of the core structure are not important for the content of the present article.

For better understanding of the superfluidity phenomenon it is useful to consider a mechanical analog of superfluid current (Sonin, 1982). Let us twist a long elastic rod so that a twisting angle at one end of the rod with respect to an opposite end reaches values many times 2π . Bending the rod into a ring and connecting the ends rigidly, one obtains a ring with a circulating persistent angular-momentum flux (Fig. 4). The flux is proportional to the gradient of twisting angle, which plays the role of the phase gradient in the supercurrent. The deformed state of the ring is not the ground state of the ring, but it cannot relax to the ground state

Fig. 4 Mechanical analog of a persistent current: A twisted elastic rod bent into a closed ring. There is a persistent angular-momentum flux around the ring. From Sonin EB (2010) Spin currents and spin superfluidity. *Advances in Physics* 59: 181–255.

via any elastic process, because it is topologically stable. The only way to relieve the strain inside the rod is *plastic displacements*. This means that dislocations start to move across rod cross-sections. The role of dislocations in the twisted rod is similar to the role of vortices in the superfluid.

Spin superfluidity in ferromagnets

For a ferromagnet with magnetization density $\mathbf{M}$ the LLG equation is (Landau and Lifshitz, 1980)

$$\frac{\partial \mathbf{M}}{\partial t} = \gamma [\mathbf{H}_{\text{eff}} \times \mathbf{M}], \quad (17)$$

where γ is the gyromagnetic ratio between the magnetic and mechanical moment. The effective magnetic field is determined by the functional derivative of the Hamiltonian $\mathcal{H}$:

$$\mathbf{H}_{\text{eff}} = -\frac{\delta \mathcal{H}}{\delta \mathbf{M}} = -\frac{\partial \mathcal{H}}{\partial \mathbf{M}} + \nabla_i \frac{\partial \mathcal{H}}{\partial \nabla_i \mathbf{M}} \quad (18)$$

According to the LLG equation, the absolute value M of the magnetization does not vary. The evolution of $\mathbf{M}$ is a precession around the effective magnetic field $\mathbf{H}_{\text{eff}}$.

If spin-rotational invariance is broken and there is uniaxial crystal magnetic anisotropy the phenomenological Hamiltonian is

$$\mathcal{H} = \frac{A}{2} \nabla_i \mathbf{M} \cdot \nabla_i \mathbf{M} + \frac{GM_z^2}{2M^2} - \mathbf{H} \cdot \mathbf{M}. \quad (19)$$

The parameter A is stiffness of the spin system determined by exchange interaction. If the anisotropy parameter G is positive, it is the “easy plane” anisotropy, which keeps the magnetization in the xy plane. If the external magnetic field $\mathbf{H}$ is directed along the z axis, the z component of spin is conserved because of invariance with respect to rotations around the z axis. For the sake of simplicity we ignore the magnetostatic energy, which depends on sample shape.

Since the absolute value M of magnetization is fixed, the magnetization vector $\mathbf{M}$ is fully determined by the z magnetization component M_z and the angle φ showing the direction of $\mathbf{M}$ in the easy plane xy :

$$M_x = M_{\perp} \cos \varphi, \quad M_y = M_{\perp} \sin \varphi, \quad M_{\perp} = \sqrt{M^2 - M_z^2}. \quad (20)$$

In the new variables the Hamiltonian is

$$\mathcal{H} = \frac{AM_{\perp}^2 (\nabla \varphi)^2}{2} + \frac{M_z^2}{2\chi} - HM_z. \quad (21)$$

Here we neglected gradients of M_z . The magnetic susceptibility $\chi = M^2/G$ along the z axis is determined by the easy-plane anisotropy parameter G . The LLG equation reduces to the Hamilton equations for a pair of canonically conjugate continuous variables “angle–moment”:

$$\frac{1}{\gamma} \frac{d\varphi}{dt} = -\frac{\delta\mathcal{H}}{\delta M_z} = -\frac{\partial\mathcal{H}}{\partial M_z}, \quad (22)$$

$$\frac{1}{\gamma} \frac{dM_z}{dt} = \frac{\delta\mathcal{H}}{\delta\varphi} = -\nabla \cdot \frac{\partial\mathcal{H}}{\partial \nabla\varphi}, \quad (23)$$

where functional derivatives are taken from the Hamiltonian Eq. (21). Using the expressions for functional derivatives the Hamilton equations are

$$\frac{1}{\gamma} \frac{d\varphi}{dt} = AM_z(\nabla\varphi)^2 - \frac{M_z - \chi H}{\chi}, \quad (24)$$

$$\frac{1}{\gamma} \frac{dM_z}{dt} + \nabla \cdot \mathbf{J}_s = 0, \quad (25)$$

where

$$\mathbf{J}_s = -\frac{\partial\mathcal{H}}{\partial \nabla\varphi} = -AM_\perp^2 \nabla\varphi \quad (26)$$

is the spin current. Although our equations are written for magnetization, but not for the spin density, $\mathbf{J}_s$ is defined as a current of spin with the spin density M_z/γ .

There is an evident analogy of Eqs. (24) and (25) with the hydrodynamic equations (4) and (5) for the superfluid. This analogy of magnetodynamics with hydrodynamics was pointed out by Halperin and Hohenberg (1969) for spin waves in antiferromagnets. The analogy is also important for spin superfluidity.

There are linear solutions of Eqs. (24) and (25) describing the plane spin-wave mode $\propto e^{ik \cdot r - i\omega t}$ with the sound-like spectrum:

$$\omega = c_{sw}k, \quad (27)$$

where

$$c_{sw} = \gamma M_\perp \sqrt{\frac{A}{\chi}} \quad (28)$$

is the spin-wave velocity in the ground state. The variation of the phase in the space is the same as in the sound mode propagating in the superfluid and shown in Fig. 1(a).

However, as well as the mass current in a sound wave, the small oscillating spin current in the spin wave does not lead to long-distance superfluid spin transport, which this article addresses. Spin superfluid transport on long distances is realized in current states with spin performing a large number of full 2π -rotations in the easy plane as shown in Fig. 1(b). In the current state with a constant gradient of the spin phase $\mathbf{K} = \nabla\varphi$, there is a constant magnetization component along the magnetic field (the axis z):

$$M_z = \frac{\chi H}{1 - \chi A K^2}. \quad (29)$$

Like in superfluids, the stability of current states is connected with topology of the order parameter space. In isotropic ferromagnets ($G = 0$) the order parameter space is a spherical surface of radius equal to the absolute value of the magnetization vector $\mathbf{M}$ [Fig. 5(a)]. All points on this surface correspond to the same energy of the ground state. Suppose we created the spin current state with monotonously varying phase φ in a torus. This state maps on the equatorial circumference in the order parameter space. The topology allows to continuously shift the circumference and to reduce it to a point (the northern or the southern pole). During this process shown in Fig. 5(a) the path remains in the order parameter space all the time, and therefore, no energetic barrier resists to the transformation. Thus, in isotropic ferromagnets the metastable current state are not expected.

In a ferromagnet with easy-plane anisotropy ($G > 0$) the order parameter space reduces from the spherical surface to a circumference parallel to the xy plane. It is shown in Fig. 5(b) for zero magnetic field when the circumference is the equator. This order parameter space is topologically equivalent to that in superfluids. Now the transformation of the circumference to the point costs the anisotropy energy. This allows to expect metastable spin currents (supercurrents). The magnetic field along the anisotropy axis z shifts the easy plane either up [Fig. 5(d)] or down away from the equator.

In order to check the Landau criterion, one should know the spectrum of spin waves in the current state with the constant value of the spin phase gradient $\mathbf{K} = \nabla\varphi$ and with the longitudinal (along the magnetic field) magnetization given by Eq. (29). The spectrum is determined by solving the Hamilton equations Eqs. (24) and (25) linearized with respect to weak perturbations of the current state. We skip the standard algebra given elsewhere (Sonin, 2019b). Finally one obtains (Iacocca et al., 2017; Sonin, 2019b) the spectrum of plane spin waves:

$$\omega + \mathbf{w} \cdot \mathbf{k} = \tilde{c}_{sw}k. \quad (30)$$

Here

$$\tilde{c}_{sw} = \sqrt{1 - \chi A K^2} c_{sw} \quad (31)$$

is the spin-wave velocity in the current state, and the spin wave velocity c_{sw} in the ground state is given by Eq. (28). The velocity

$$\mathbf{w} = 2\gamma M_z A \mathbf{K} \quad (32)$$

Fig. 5 Mapping of spin current states on the order parameter space of the ferromagnet. (a) Spin current in an isotropic ferromagnet. The current state in torus maps on an equatorial circumference on the sphere of radius M (top). Continuous shift of mapping on the surface of the sphere (middle) reduces it to a point at the northern pole (bottom), which corresponds to the ground state without currents. (b) Spin current in an easy-plane ferromagnet at $M_z = 0$. The easy-plane anisotropy reduces the order parameter space to an equatorial circumference in the xy plane topologically equivalent to the order parameter space in superfluids. (c) Spin current state with a magnetic vortex in an easy-plane ferromagnet at $M_z = 0$. The states map on the surface of the upper or the lower hemisphere. (d) Spin current in an easy-plane ferromagnet at $M_z \neq 0$. Spin is confined in the plane parallel to the xy plane but shifted closer to the northern pole. A nonzero M_z appears either in the equilibrium due to a magnetic field parallel to the axis z , or due to spin pumping. (e) Spin current state with a magnetic vortex in an easy-plane ferromagnet at $M_z \neq 0$. The state maps on the surface of the upper or the lower parts of the sphere. Two options of mapping are not degenerate, and the phase slip with the magnetic vortex of a smaller energy (a smaller area of mapping) is more probable. From Sonin EB (2020) Superfluid spin transport in magnetically ordered solids (review article). *Fizika Nizkikh Temperatur* 46: 523–535, [Low Temp. Phys. 46, 436 (2020)].

can be called Doppler velocity because its effect on the frequency is similar to the Doppler effect in a Galilean invariant fluid [see the text before Eq. (10)]. However, our system is not Galilean invariant (Iacocca et al., 2017), and this is the pseudo Doppler effect. Because of it, the gradient K proportional to w is present also on the right-hand side of the dispersion relation Eq. (30).

We obtained the gapless Goldstone mode with the sound-like linear in k spectrum. The current state becomes unstable when at k antiparallel to w the frequency ω becomes negative. This happens at the gradient K equal to the Landau critical gradient

$$K_L = \frac{M_{\perp}}{\sqrt{4M^2 - 3M_{\perp}^2}} \frac{1}{\sqrt{\chi A}}. \quad (33)$$

In the limit of weak magnetic fields when $M_z \ll M$ the Landau critical gradient is

$$K_L = \frac{1}{\sqrt{\chi A}} = \frac{\gamma M}{\chi c_{sw}}. \quad (34)$$

In this limit the pseudo-Doppler effect is not important, and at the Landau critical gradient K_L the spin-wave velocity $\tilde{c}_{sw}$ in the current state vanishes.

In the opposite limit $M_z \rightarrow M$ ($M_{\perp} \rightarrow 0$) the Landau critical gradient,

$$K_L = \frac{M_{\perp}}{2M} \frac{1}{\sqrt{\chi A}}, \quad (35)$$

decreases, and the spin superfluidity becomes impossible at the phase transition to the easy-axis anisotropy ($M_{\perp} = 0$).

Deriving the sound-like spectrum of the spin wave we neglected in the Hamiltonian terms dependent on gradients ∇M_z . One should take into account these terms at the wavelength on the order of the coherence length

$$\xi_0 = \frac{M}{M_{\perp}} \sqrt{\chi A} = \frac{M^2}{M_{\perp}} \sqrt{\frac{A}{G}}. \quad (36)$$

The Landau critical gradient K_L is on the order of the inverse coherence length $1/\xi_0$.

The current states relax to the ground state via phase slips events, in which magnetic vortices cross spin current streamlines. At $M_z = 0$ the current state with a magnetic vortex maps on a surface of a hemisphere of radius M either above or below the equator (Nikiforov and Sonin, 1983) as shown in Fig. 5(c). The vortex core has a structure of a skyrmion. The skyrmion mapping on a hemisphere is called meron. At $M_z = 0$ two magnetic vortices with opposite spin polarizations have the same energy, and both can participate in phase slips. But at $M_z \neq 0$ the magnetic vortex with a smaller mapping area [Fig. 5(e)] has a smaller energy, and phase slips with its participation are more frequent. Since inside the core the gradients ∇M_z cannot be ignored, the core radius is on the order of the coherence length ξ_0 . Variation of the magnetization direction in space inside the skyrmion core is schematically shown

Fig. 6 Skyrmion cores of magnetic vortices. Variation of magnetization vectors ($\mathbf{M}$ in a ferromagnet, $\mathbf{M}_1$ and $\mathbf{M}_2$ in an antiferromagnet) in the vortex core as a function of the distance r from the vortex axis is shown schematically. Horizontal directions of magnetizations correspond to the direction of the z axis in the spin space. (a) The magnetic vortex in the ferromagnet corresponding to the gapless Goldstone spin wave mode with the coherence length ξ_0 given by Eq. (36). (b) The magnetic vortex in the antiferromagnet corresponding to the Goldstone spin wave mode with the coherence length ξ_0 given by Eq. (59). (c) The magnetic vortex in the antiferromagnet corresponding to the gapped spin wave mode with the coherence length ξ given by Eq. (61). From Sonin EB (2019a) Interplay of spin and mass superfluidity in antiferromagnetic spin-1 Bose–Einstein condensates and bicirculation vortices. *Physical Review Research* 1: 033103.

in Fig. 6(a). One can find more details and numerical calculations of the structure of skyrmion cores of magnetic vortices in ferromagnets elsewhere (Sonin, 2018).

The estimation of barriers for phase slips in spin-superfluid ferromagnets is similar to that in the case of mass superfluidity. The spin phase gradient in the current state with a straight magnetic vortex parallel to the axis z is

$$\nabla\varphi = \frac{[\hat{z} \times \mathbf{r}]}{r^2} + \mathbf{K}. \quad (37)$$

We consider a 2D problem of the straight magnetic vortex at the distance r_m from the plane border. The gradient $\mathbf{K}$ is parallel to the border. Substituting the phase gradient field Eq. (37) into the kinetic energy and integrating the energy over the London region, where $M_\perp$ is close to its value in the ground state, one obtains the energy of the magnetic vortex per unit length:

$$\tilde{\varepsilon}_v = \pi A M_\perp^2 \left(\ln \frac{r_m}{r_c} - 2K r_m \right). \quad (38)$$

The magnetic vortex energy has a maximum at $r_m = 1/2K$. The energy at the maximum is a barrier preventing phase slips:

$$\varepsilon_b = \pi A M_\perp^2 \ln \frac{1}{2K r_c}. \quad (39)$$

The barrier vanishes if the gradient K becomes of the order of the inverse vortex core radius r_c . This gradient is on the order of the Landau critical gradient K_L .

Considering mapping of current states with nonzero magnetization M_z [Fig. 5(d) and (e)], we had in mind the equilibrium magnetization $M_z = \chi H$ produced by an external magnetic field $\mathbf{H}$. In the equilibrium there is no precession of the magnetization $\mathbf{M}$ around the axis z . However, non-equilibrium states with non-equilibrium magnetization M_z , which makes the magnetization (spin) to coherently precess, are also possible. One can create them by pumping of magnons, which bring spin and energy into the system. Spin pumping compensates inevitable losses of spin due to spin relaxation. However, usually the process of spin relaxation is weak, and one may treat the coherent precession state as a quasi-equilibrium state at fixed M_z . The coherent precession state does not require the crystal easy-plane anisotropy for its existence. The easy-plane topology of Fig. 5(d) is provided dynamically, and, as a result, metastable spin current states are also possible.

Spin superfluidity in the quasi-equilibrium coherent precession state was investigated theoretically and experimentally in the B phase of superfluid ^3He (Bunkov, 1995). Later the coherent precession state in ^3He was rebranded as magnon BEC (Bunkov and Volovik, 2013). Coherent spin precession state (also under the name of magnon BEC) was revealed also in YIG magnetic films (Demokritov et al., 2006). Spin superfluidity in YIG was discussed by Sun et al. (2016, 2017) and Sonin (2017). In the quasi-equilibrium coherent precession state demonstration of the long-distance superfluid spin transport is problematic (see Section “Experiments on detection of spin superfluidity”). Semantic dilemma “coherent precession state, or magnon BEC” was discussed by Sonin (2010).

Spin superfluidity in antiferromagnets

The dynamics of a bipartite antiferromagnet can be described by the LLG equations for two spin sublattices coupled via exchange interaction (Keffer and Kittel, 1951):

$$\frac{d\mathbf{M}_i}{dt} = \gamma[\mathbf{H}_i \times \mathbf{M}_i]. \quad (40)$$

Here the subscript $i = 1, 2$ indicates to which sublattice the magnetization $\mathbf{M}_i$ belongs, and

$$\mathbf{H}_i = -\frac{\delta\mathcal{H}}{\delta\mathbf{M}_i} = -\frac{\partial\mathcal{H}}{\partial\mathbf{M}_i} + \nabla_j \frac{\partial\mathcal{H}}{\partial\nabla_j\mathbf{M}_i} \quad (41)$$

is the effective field for the i th sublattice determined by the functional derivative of the Hamiltonian $\mathcal{H}$. For an isotropic antiferromagnet the Hamiltonian is

$$\mathcal{H} = \frac{\mathbf{M}_1 \cdot \mathbf{M}_2}{\chi} + \frac{A(\nabla_i \mathbf{M}_1 \cdot \nabla_i \mathbf{M}_1 + \nabla_i \mathbf{M}_2 \cdot \nabla_i \mathbf{M}_2)}{2} + A_{12} \nabla_j \mathbf{M}_1 \cdot \nabla_j \mathbf{M}_2 - \mathbf{H} \cdot \mathbf{m}. \quad (42)$$

The total magnetization is

$$\mathbf{m} = \mathbf{M}_1 + \mathbf{M}_2, \quad (43)$$

and the staggered magnetization

$$\mathbf{L} = \mathbf{M}_1 - \mathbf{M}_2 \quad (44)$$

is normal to $\mathbf{m}$.

In the LLG theory absolute values of sublattice magnetizations $\mathbf{M}_1$ and $\mathbf{M}_2$ are equal to constant M , and in the uniform state without gradients the Hamiltonian is

$$\mathcal{H} = -\frac{M^2}{\chi} + \frac{m^2}{2\chi} - Hm_z. \quad (45)$$

Here and later on we assume that the magnetic field is applied along the z axis. The constant term M^2/χ can be ignored. In the ground state the total magnetization $\mathbf{m}$ is directed along the magnetic field (the z axis), and the staggered magnetization $\mathbf{L}$ is confined to the xy plane.

The order parameter for an antiferromagnet is the unit Néel vector $\mathbf{l} = \mathbf{L}/L$. The order parameter space for the isotropic antiferromagnet in the absence of the external magnetic field is a surface of a sphere, as for isotropic ferromagnets. But in ferromagnets the magnetic field produces an easy axis for the magnetization, while in the antiferromagnet the magnetic field produces the easy plane for the order parameter vector $\mathbf{l}$. Thus, the easy-plane topology necessary for the spin superfluidity in antiferromagnets does not require the crystal easy-plane anisotropy.

In the analogy to the ferromagnetic case, one can describe the vectors of sublattice magnetizations $\mathbf{M}_i$ with the constant absolute value M by the two pairs of the conjugate variables (M_{iz}, φ_i) , which are determined by the two pairs of the Hamilton equations:

$$\frac{1}{\gamma} \frac{d\varphi_i}{dt} = -\frac{\delta\mathcal{H}}{\delta M_{iz}} = -\frac{\partial\mathcal{H}}{\partial M_{iz}}, \quad (46)$$

$$\frac{1}{\gamma} \frac{dM_{iz}}{dt} = \frac{\delta\mathcal{H}}{\delta\varphi_i} = \frac{\partial\mathcal{H}}{\partial\varphi_i} - \nabla \cdot \frac{\partial\mathcal{H}}{\partial\nabla\varphi_i}. \quad (47)$$

Let us consider the magnetization distribution with axial symmetry around the axis z :

$$\begin{aligned} M_{1z} = M_{2z} = \frac{m_z}{2} = M \sin \theta_0, \quad m_x = m_y = 0, \\ M_{1x} = -M_{2x} = \frac{L}{2} \cos \varphi, \\ M_{1y} = -M_{2y} = \frac{L}{2} \sin \varphi, \quad L_z = 0. \end{aligned} \quad (48)$$

Here $\varphi = \varphi_1 = \pi - \varphi_2$ is the angle of rotation of $\mathbf{L}$ around the z axis, $L = \sqrt{4M^2 - m_z^2} = 2M \cos \theta_0$, and θ_0 is the canting angle. The Hamiltonian Eq. (42) for the axisymmetric case becomes the Hamiltonian

$$\mathcal{H} = \frac{m_z^2}{2\chi} - Hm_z + \frac{A_- L^2 (\nabla\varphi)^2}{4} \quad (49)$$

for the pair of the canonically conjugate variables (m_z, φ) . The Hamilton equations for this pair are

$$\frac{1}{\gamma} \frac{d\varphi}{dt} = \frac{A_- m_z (\nabla\varphi)^2}{2} - \frac{m_z - \chi H}{\chi}, \quad (50)$$

$$\frac{1}{\gamma} \frac{dm_z}{dt} + \nabla \cdot \mathbf{J}_s = 0. \quad (51)$$

Here $A_- = A - A_{12}$, and

$$J_s = -\frac{A_- L^2}{2} \nabla \varphi \quad (52)$$

is the superfluid spin current. These equations are identical to Eqs. (24)–(26) for the ferromagnet after replacing the spontaneous magnetization component M_z by the total magnetization component m_z , A by $A_-/2$, and $M_\perp$ by L .

In the stationary spin current state there is a constant gradient $\mathbf{K} = \nabla \varphi$ of the spin phase and a constant total magnetization

$$m_z = \frac{\chi H}{1 - \chi A_- K^2/2}. \quad (53)$$

For checking the Landau criterion we must know the spectrum of all collective modes. Solution of Eqs. (50) and (51) linearized with respect to plane wave perturbations $m' \propto e^{i\mathbf{k}\cdot\mathbf{r}-i\omega t}$ and $\varphi' \propto e^{i\mathbf{k}\cdot\mathbf{r}-i\omega t}$ of the stationary spin current state yield the spectrum of the Goldstone gapless mode:

$$\omega + \mathbf{w} \cdot \mathbf{k} = \tilde{c}_{sw} k. \quad (54)$$

Here the spin-wave velocity $\tilde{c}_{sw}$ in the current state and the Doppler velocity $\mathbf{w}$ are

$$\tilde{c}_{sw} = c_{sw} \sqrt{1 - \frac{\chi A_- K^2}{2}}, \quad \mathbf{w} = \gamma m_z A_- \mathbf{K}, \quad (55)$$

while

$$c_{sw} = \gamma L \sqrt{\frac{A_-}{2\chi}} = 2\gamma M \cos \theta_0 \sqrt{\frac{A_-}{2\chi}} \quad (56)$$

is the spin-wave velocity in the ground state without spin currents. The difference between gapless modes in a ferromagnet and an antiferromagnet is that in the former the total magnetization precesses around the z axis, while in the latter there is the precession of the staggered magnetization. Oscillations of sublattice magnetizations $\mathbf{M}_1$ and $\mathbf{M}_2$ in the gapless mode are illustrated in Fig. 7(a).

In antiferromagnets there is another mode in which the total magnetization $\mathbf{m}$ and the staggered magnetization $\mathbf{L}$ perform rotational oscillations around the axis normal to the axis z . Without spin supercurrents this axis does not vary in space, and one can choose it to be the axis y . The oscillations of the sublattice magnetizations are illustrated in Fig. 7(b). In the spin current state $\mathbf{L}$ rotates around the axis, which itself rotates in the easy-plane xy along the current streamlines. The magnetic field breaks invariance with respect to rotations around axes normal to the field, and the mode spectrum is

$$\omega + \mathbf{w} \cdot \mathbf{k} = \sqrt{\omega_0^2 + c_{sw}^2 k^2}, \quad (57)$$

where the gap is given by

$$\omega_0 = \sqrt{\frac{\gamma^2 m_z^2}{\chi^2} - c_{sw}^2 K^2}. \quad (58)$$

More details of the derivation are given by Sonin (2019b).

Applying the Landau criterion to the gapless mode at small canting angles θ_0 (weak magnetic fields), one obtains the critical gradient K_L and the correlation length ξ_0 ,

$$K_L = \frac{1}{\xi_0}, \quad \xi_0 = \sqrt{\frac{\chi A_-}{2}}, \quad (59)$$

similar to those obtained for a ferromagnet [Eqs. (35) and (36)]. However, in contrast to a ferromagnet where the susceptibility χ is connected with weak anisotropy energy, in an antiferromagnet the susceptibility χ is determined by a much larger exchange energy

Fig. 7 The schematic picture of the two spin wave modes in the bipartite antiferromagnet in the plane xz . (a) The gapless Goldstone mode. There are oscillations of the canting angle determining the magnetization component m_z and rotational oscillations around the axis z . (b) The gapped mode. There are rotational oscillations of the two magnetizations around the axis y . From Sonin EB (2020) Superfluid spin transport in magnetically ordered solids (review article). *Fizika Nizkikh Temperatur* 46: 523–535, [Low Temp. Phys. 46, 436 (2020)].

and is rather small. As a result, in the antiferromagnet the gapped mode loses its stability at much lower values of K than the gapless mode. This happens at the Landau critical gradient

$$K_L = \frac{1}{\xi} \quad (60)$$

when the gap given by Eq. (58) vanishes and the mode frequency becomes complex. Here we introduced a new correlation length

$$\xi = \frac{c_s}{\gamma H} = \frac{\chi c_s}{\gamma m_z}. \quad (61)$$

As usual, the instability with respect to phase slips with magnetic vortices starts at the gradients of the same order as the Landau critical gradient. Two modes in antiferromagnets have different correlation lengths, and, correspondingly, there are two types of magnetic vortices with different structure and size of the skyrmion core. Fig. 6(b) shows schematically spatial variation of the sublattice magnetizations in the skyrmion core of a magnetic vortex connected with the Goldstone gapless mode. The core radius is of the order of the correlation length ξ_0 given by Eq. (59). Inside the core the canting angle θ_0 grows and reaches $\pi/2$ at the vortex axis. This transforms an antiferromagnet to a ferromagnet with the magnetization $2M$. The transformation increases the exchange energy, and at weak magnetic fields creation of magnetic vortices connected with the gapped mode starts earlier. Its core size is determined by the larger correlation length ξ determined by the Zeeman energy and given by Eq. (61). The skyrmion core connected with the gapped mode is illustrated in Fig. 6(c).

Superfluid spin transport without spin conservation law

Though processes violating the spin conservation law are relativistically weak, their effect is of principal importance and cannot be ignored in general. Here we consider the effect of broken rotational symmetry in the easy plane in ferromagnets. Its extension on antiferromagnets requires insignificant modifications. One should add the s -fold in-plane anisotropy energy $\propto G_{in}$ to the Hamiltonian (21), which becomes

$$\mathcal{H} = \frac{M_z^2}{2\chi} - \gamma M_z H + \frac{AM_\perp^2 (\nabla\varphi)^2}{2} + G_{in} [1 - \cos(s\varphi)]. \quad (62)$$

Then the spin continuity equation (25) becomes

$$\frac{dM_z}{dt} = -\nabla \cdot \mathbf{J}_s + sG_{in} \sin(s\varphi) = AM_\perp^2 \left[\nabla^2 \varphi - \frac{\sin(s\varphi)}{l^2} \right], \quad (63)$$

where

$$l = \sqrt{\frac{AM_\perp^2}{sG_{in}}} \quad (64)$$

is the thickness of the wall separating domains with s equivalent easiest directions in the easy plane. In the stationary spin current states $dM_z/dt = 0$, and the phase φ is a periodical solution of the sine-Gordon equation parametrized by the average phase gradients $\langle \nabla\varphi \rangle$. At small $\langle \nabla\varphi \rangle \ll 1/l$ the spin structure constitutes the chain of domains with the period $2\pi/s \langle \nabla\varphi \rangle$. Spin currents (gradients) inside domains are negligible but there are spin currents inside domain walls. The spin current has a maximum in the center of the domain wall equal to

$$J_l = \sqrt{\frac{2A}{s}} \frac{1}{l}. \quad (65)$$

The spin transport in the case $\langle \nabla\varphi \rangle \ll 1/l$ hardly reminds the superfluid transport on macroscopic scales: spin is transported over distances on the order of the domain-wall thickness l . With increasing $\langle \nabla\varphi \rangle$ the density of domain walls grows, and at $\langle \nabla\varphi \rangle \gg 1/l$ the domains coalesce. Deviations of the gradient $\nabla\varphi$ from the constant average gradient $\langle \nabla\varphi \rangle$ become negligible. This restores the analogy with the superfluid transport in superfluids (Sonin, 1978a,b, 1982), and spin non-conservation can be ignored. The transformation of the domain wall chain into a weakly inhomogeneous current state at growing $\langle \nabla\varphi \rangle$ is illustrated in Fig. 8. According to the Landau criterion, spin current states become unstable at $\nabla\varphi \sim 1/\xi_0$, where the correlation length ξ_0 is given by Eq. (36). Thus, one can expect metastable nearly uniform current states at $1/l \ll \langle \nabla\varphi \rangle \ll 1/\xi_0$. This is possible if the easy plane anisotropy energy G essentially exceeds the in-plane anisotropy energy G_{in} .

In the limit $\nabla\varphi \ll 1/l$ of strongly nonuniform current states the decay of the current is also possible only via phase slips, but the structure of magnetic vortices is essentially different from that in the opposite limit $\nabla\varphi \gg 1/l$. The magnetic vortex is a line defect at which s domain walls end. The phase slip with the magnetic vortex crossing the streamlines in the channel leads to annihilation of s domain walls. This process is illustrated in Fig. 2(b) for the fourfold in-plane symmetry ($s = 4$).

An important difference with conventional mass superfluidity is that while the existence of conventional superfluidity is restricted only from above by the Landau critical gradients, the spin superfluidity is restricted also from below: gradients should

Fig. 8 The nonuniform spin-current states with $\langle \nabla \varphi \rangle \ll 1/l$ and $\langle \nabla \varphi \rangle \gg 1/l$. From Sonin EB (2010) Spin currents and spin superfluidity. *Advances in Physics* 59: 181–255.

not be less than the value $1/l$. Thus, the gradient $K = \langle \nabla \varphi \rangle$ in the expression Eq. (39) barrier height cannot be less than $1/l$, and the height of the barrier cannot exceed

$$\varepsilon_m = \pi A M_{\perp}^2 \ln \frac{l}{r_c}. \quad (66)$$

In contrast to the maximal phase slip barrier Eq. (16) in mass superfluidity, in spin superfluidity the maximal phase slip barrier does not become infinite in the macroscopic limit $W \rightarrow \infty$ (König et al., 2001; Sonin, 1978a,b, 1982).

Long-distance superfluid spin transport

The absence of the strict spin conservation law also leads to the dissipative process, which is impossible in the mass superfluidity and very important for long-distance superfluid spin transport (Sonin, 1978a, 2010; Takei et al., 2014; Takei and Tserkovnyak, 2014): longitudinal spin relaxation characterized in the magnetism theory by the Bloch time T_1 . Taking the Bloch relaxation into account, the equation for the non-equilibrium magnetization $M'_z = M_z - \chi H$ becomes.

$$\frac{1}{\gamma} \frac{dM'_z}{dt} = -\nabla \cdot \mathbf{J} - \frac{M'_z}{\gamma T_1}. \quad (67)$$

Here the total current $\mathbf{J} = \mathbf{J}_s + \mathbf{J}_d$ includes not only the spin supercurrent $\mathbf{J}_s$ given by Eq. (26), but also the spin diffusion current

$$\mathbf{J}_d = -\frac{D}{\gamma} \nabla M_z. \quad (68)$$

In the absence of spin superfluidity ($\mathbf{J}_s = 0$) Eq. (67) describes pure spin diffusion [Fig. 9(a)]. Its solution, with the boundary condition that the spin current J_0 is injected at the interface $x = 0$, is

$$J_d = J_0 e^{-x/L_d}, \quad M'_z = \gamma J_0 \sqrt{\frac{T_1}{D}} e^{-x/L_d}, \quad (69)$$

where

$$L_d = \sqrt{DT_1} \quad (70)$$

is the spin-diffusion length. Thus, the effect of spin injection exponentially decays at the scale of the spin-diffusion length, and the density of spin accumulated at the other border of the medium decreases exponentially with growing distance d .

However, if spin superfluidity is possible, the spin precession equation Eq. (24) becomes relevant. According to this equation, in a stationary state the magnetization M'_z cannot vary in space [Fig. 9(b)] since the gradient $\nabla M'_z$ leads to the linear in time growth of the gradient $\nabla \varphi$. The right-hand side of Eq. (24) is an analog of the chemical potential, and the requirement of constant in space magnetization M_z is similar to the requirement of constant in space chemical potential in superfluids, or the electrochemical potential in superconductors. As a consequence of this requirement, spin diffusion current is impossible in the bulk since it is simply “short-circuited” by the superfluid spin current. The bulk spin diffusion current can appear only in AC processes.

If the spin superfluidity is possible, the spin current can reach the spin detector at the plane $x = d$ opposite to the border where spin is injected. As a boundary condition at $x = d$, one can use a phenomenological relation $J_s(d) = M'_z(d) v_d$ connecting the spin

Fig. 9 Long distance spin transport. (a) Injection of the spin current J_0 into a spin-non-superfluid medium. (b) Injection of the strong spin current $J_0 \gg J_l$ into a spin-superfluid medium. (c) Injection of the weak spin current $J_0 < J_l$ into a spin-superfluid medium. From Sonin EB (2010) Spin currents and spin superfluidity. *Advances in Physics* 59: 181–255.

current with the non-equilibrium magnetization at the border with a non-magnetic medium. Here v_d is a phenomenological constant. This boundary condition (Sonin, 1978a) was confirmed by the microscopic theory of Takei and Tserkovnyak (2014). Together with the boundary condition $J_s(0) = J_0$ at $x = 0$ this yields the solution of Eqs. (24) and (67):

$$M'_z = \frac{T_1}{d + v_d T_1} \gamma J_0, \quad J_s(x) = J_0 \left(1 - \frac{x}{d + v_d T_1} \right). \quad (71)$$

Thus, the spin accumulated at large distance d from the spin injector slowly decreases with d as $1/(d + C)$ [Fig. 9(b)], in contrast to the exponential decay $\propto e^{-d/l_d}$ in the spin diffusion transport [Fig. 9(a)]. The constant C is determined by the boundary condition at $x = d$.

The long-distance superfluid spin transport is possible only if the injected spin current is not too small. If the injection spin current J_0 is less than the current J_l determined by Eq. (65) the superfluid spin current penetrates into the medium only at distances not longer than the width l of a domain wall in a non-uniform spin current state at a very small average gradient $\langle \nabla \varphi \rangle \ll 1/l$ [Fig. 9(c)]. This threshold for the long-distance spin superfluid transport is connected with the absence of the strict conservation law for spin (Section “Superfluid spin transport without spin conservation law”).

Experiments on detection of spin superfluidity

Experimental detection of spin superfluidity does not reduce to experimental evidence of the existence of spin supercurrents proportional to gradients of spin phase. As pointed out in Introduction (Section “Introduction”), such supercurrents produced by spin phase difference smaller than 2π emerge in any non-uniform spin structure. Numerous observations of spin waves and domain structures during the more than half-a-century history of modern magnetism cannot be explained without these microscopic spin currents. Only detection of macroscopical spin supercurrents produced by the phase difference many times larger than 2π is evidence of spin superfluidity.

The experimental evidence of macroscopical spin supercurrents was obtained in the past in the B phase of superfluid ^3He (Borovik-Romanov et al., 1987). A spin current was generated in a long channel connecting two cells filled by $^3\text{He} - B$. The quasi-equilibrium state of the coherent spin precession was supported by spin pumping. The magnetic fields applied to the two cells were slightly different, and therefore, the spins in the two cells precessed with different frequencies. A small difference in the frequencies leads to a linear growth of difference of the precession phases in the cells and a phase gradient in the channel. When the gradient reached the critical value, 2π phase slips were detected. This was evidence of non-trivial spin supercurrents.

This experiment was done in the dynamical state of coherent spin precession (non-equilibrium magnon BEC). The states require pumping of spin in the whole bulk for their existence. In the geometry of the experiment on long-distance spin transport (Section “Long-distance superfluid spin transport”) this would mean that spin is permanently pumped not only by a distant

Fig. 10 Long distance spin transport in the experiment by Yuan et al. (2018). Spin is injected from the left Pt wire and flows along the Cr_2O_3 film to the right Pt wire, which serves as a detector. The arrowed dashed line shows a spin-current streamline. From Sonin EB (2020) Superfluid spin transport in magnetically ordered solids (review article). *Fizika Nizkikh Temperatur* 46: 523–535, [Low Temp. Phys. 46, 436 (2020)].

injector but also all the way up to the place where its accumulation is probed. Thus, the spin detector measures not only spin coming from the distant injector but also spin pumped close to the detector. Therefore, the experiment cannot demonstrate the existence of long-distance superfluid spin transport, but can provide, nevertheless, indirect evidence that long-distance superfluid spin transport is possible in principle.

The experiment on detection of long-distance superfluid spin transport (Section “Long-distance superfluid spin transport”) was recently done by Yuan et al. (2018) in antiferromagnetic Cr_2O_3 . The spin was injected from a Pt injector by heating [the Seebeck effect (Seki et al., 2015)] on one side of the Cr_2O_3 film and spin accumulation was probed on another side of the film by the Pt detector via the inverse spin Hall effect (Fig. 10). In agreement with the theoretical prediction, they observed spin accumulation inversely proportional to the distance from the interface where spin was injected.

In the experiment of Yuan et al. (2018) spin injection required heating of the Pt injector, and the spin current to the detector is inevitably accompanied by a heat flow. Lebrun et al. (2018) argued that Yuan et al. (2018) detected a signal not from spin coming from the distant injector but from spin generated by the Seebeck effect at the interface between the heated antiferromagnet and the Pt detector. If true, Yuan et al. (2018) observed not long-distance spin transport but long-distance heat transport. A resolution of this controversy requires further experimental and theoretical investigations. In particular, one could check long-distance heat transport scenario by replacing the Pt spin injector in the experiment of Yuan et al. (2018) by a heater, which produces heat but no spin.

Observation of the long-distance superfluid spin transport was also reported by Stepanov et al. (2018) in a graphene quantum Hall antiferromagnet. However, the discussion of this report requires an extensive theoretical analysis of the $\nu = 0$ quantum Hall state of graphene, which goes beyond the scope of the present article. A reader can find this analysis in Takei et al. (2016).

Conclusion

The article addressed the basics of the spin superfluidity concept: topology, Landau criterion, and phase slips. Metastable (persistent) superfluid current states are possible if the order parameter space (vacuum manifold) has the topology of a circumference like in conventional superfluids. In ferromagnets it is the circumference on the spherical surface of the spontaneous magnetizations M , and in antiferromagnets it is the spherical surface of the unit Néel vector L/L , where L is the staggered magnetization. The topology necessary for spin superfluidity requires the magnetic easy-plane anisotropy in ferromagnets, while in antiferromagnets this anisotropy is provided by the Zeeman energy, which confines the Néel vector in the plane normal to the magnetic field.

The Landau criterion was checked for the spectrum of elementary excitations, which are spin waves in our case. In ferromagnets there is only one gapless Goldstone spin wave mode. In bipartite antiferromagnets there are two modes: the Goldstone mode in which spins perform rotational oscillations around the symmetry axis and the gapped mode with rotational oscillations around the axis normal to the symmetry axis. At weak magnetic fields the Landau instability starts not in the Goldstone mode, but in the gapped mode. In contrast to superfluid mass currents in conventional superfluids, metastable spin superfluid currents are restricted not only by the Landau criterion from above but also from below. The restriction from below is related to the absence of the strict conservation law for spin.

The Landau instability with respect to elementary excitations is a precursor for the instability with respect to phase slips. The latter instability starts when the spin phase gradient reaches the value of the inverse vortex core radius. This value is on the same order of magnitude as the Landau critical gradient. Magnetic vortices participating in phase slips have skyrmion cores, which map on the upper or lower part of the spherical surface in the space of spontaneous magnetizations in ferromagnets, or in the space of the unit Néel vectors in antiferromagnets.

It is worthwhile to note that in reality it is not easy to reach the critical gradients discussed in the present article experimentally. The decay of superfluid spin currents is possible also at subcritical spin phase gradients since the barriers for phase slips can be overcome by thermal activation or macroscopic quantum tunneling. This makes the very definition of the real critical gradient rather ambiguous and dependent on duration of observation of persistent currents. Calculation of real critical gradients requires a detailed

dynamical analysis of processes of thermal activation or macroscopic quantum tunneling through phase slip barriers, which is beyond the scope of the present article. One can find examples of such analysis for conventional superfluids with mass supercurrents in Sonin (2016).

Experimental evidence of the existence of metastable superfluid spin currents in the B phase of superfluid ^3He was reported long ago (Borovik-Romanov et al., 1987). The experiment was done in the non-equilibrium state of coherent spin precession, which requires permanent spin pumping in whole bulk for its existence. This does not allow to check true long-distance superfluid spin transport without any additional spin injection on the way from an injector to a detector of spin. The experiment demonstrating the long-distance transport of spin in the solid antiferromagnet was reported recently (Yuan et al., 2018). But the interpretation of this experiment in the terms of spin superfluidity was challenged (Lebrun et al., 2018), and experimental verification of the long-distance superfluid spin transport in magnetically ordered solids convincing many (if not all) in the community is still wanted.

Mechanical analogy of the mass superfluidity discussed in the end of Section “Concept of superfluidity” is valid also for spin superfluidity. The “superfluid” flux of the angular momentum in a twisted elastic rod is similar to the superfluid spin current in magnetically ordered solids. Of course, it is not obligatory to discuss the twisted rod in terms of angular-momentum flux. More usual is to discuss it in the terms of the elasticity theory: deformations, stresses, and elastic stiffness. On the same grounds, one can avoid to use the terms “spin current” and “spin superfluidity” and consider the spin current states as metastable helicoidal spin structures determined by “phase stiffness.” This stance was quite popular in early disputes about spin superfluidity. Nowadays in the era spintronics the terms “spin supercurrents” and “spin superfluidity” are widely accepted.

In this article the essentials of spin superfluidity were discussed for simpler cases of a ferromagnet and of a bipartite antiferromagnet at zero temperature. Spin superfluidity was also investigated in antiferromagnets with a more complicated magnetic structure (Li and Kovalev, 2021). At finite temperatures the presence of the gas of incoherent magnons was taken into account in the two-fluid theory (Flebus et al., 2016) similar to the two-fluid theory in the theory of mass superfluidity.

The present article focused on spin superfluidity in magnetically ordered solids. In superfluid ^3He spin superfluidity coexists with mass superfluidity. Recently investigations of spin superfluidity were extended to spin-1 BEC, where spin and mass superfluidity also coexist and interplay (Armaitis and Duine, 2017; Lamacraft, 2017; Sonin, 2018, 2019a). This interplay leads to a number of new nontrivial features of the phenomenon of superfluidity. The both types of superfluidity are restricted by the Landau criterion for the softer collective modes, which usually are the spin wave modes. As a result, the presence of spin superfluidity diminishes the possibility of the conventional mass superfluidity. Another consequence of the coexistence of spin and mass superfluidity is phase slips with bicirculation vortices characterized by two topological charges (winding numbers) (Sonin, 2019a).

Abstract

Bose–Einstein condensation embodies some of the most fascinating aspects of quantum mechanics. Predicted 100 years ago, its experimental realization in 1995 opened up unexpected directions in both fundamental and applied quantum physics. This chapter describes the main features of Bose–Einstein condensation, focusing on its experimental realization in ultracold atomic gases. We will present the theoretical description of the effect and the main laboratory techniques used to produce and probe ultracold quantum gases, discussing both milestone experiments and emerging research directions that the theoretical and experimental investigation of Bose–Einstein condensation has opened in the recent past.

Key points

- Describe the phenomenon of Bose–Einstein condensation (BEC).
- Illustrate the experimental techniques to achieve BEC in ultracold atomic gases.
- Explain the role of atom–atom interactions in BEC.
- Discuss the connection between BEC and fundamental phenomena such as superfluidity and quantum coherence.
- Show how BEC and superfluidity can be achieved for interacting spin mixtures of ultracold Fermi gases.
- Show seminal experiments that highlighted the main properties of atomic BECs.
- Discuss emerging research directions stemming from the experimental realization of BEC in ultracold gases.

Introduction

At room temperature the behavior of a gas is governed by the laws of classical mechanics. In fact the thermal de Broglie wavelength

$$\lambda_T = \sqrt{\frac{2\pi\hbar^2}{mk_B T}} \quad (1)$$

which describes the smearing of the position of the atoms due to the Heisenberg uncertainty principle ($\hbar$ is the Planck's constant divided by 2π , k_B is the Boltzmann constant, m is the atomic mass, and T is the temperature of the gas), is much smaller than the average spacing between atoms, which then behave as classical objects. As the gas is cooled, however, the smearing increases and the

wavefunctions of adjacent atoms overlap, causing the atoms to lose their identity. If the overlap is large, the effects of quantum mechanics cannot be ignored any longer.

When quantum effects become important, it is crucial to distinguish between Bose and Fermi statistics. Bosons are particles with even total spin, and their many-body wave function is symmetric with respect to the exchange of two particles. As a consequence, bosons like to occupy the same state. Conversely fermions (particles with odd spin) are described by an antisymmetric wave function and cannot occupy the same state due to the Pauli exclusion principle. At very low temperatures, bosons and fermions behave quite differently (see Fig. 1), giving rise to distinct dynamic and thermodynamic behaviors.

Bosons are known to undergo a phase transition below a critical temperature T_c . This transition is characterized by the macroscopic occupation of a single particle state and is called *Bose–Einstein condensation*. A unique peculiarity of the transition is that it can occur even in the absence of interactions, being driven by genuine quantum statistical effects. Albert Einstein predicted the occurrence of this transition in 1924 (Einstein, 1924), on the basis of a paper of the Indian physicist S. N. Bose (Bose, 1924), devoted to the statistical description of the quanta of light. For a long time, Einstein’s predictions had no practical impact and only after the discovery of superfluidity in liquid helium in 1938, the phenomenon of Bose–Einstein condensation became again the object of theoretical investigation, with the pioneering works by London, Bogoliubov, Landau, Lifshitz, Penrose, Onsager, and Feynman.

When the temperature is low enough, all interacting systems, with the exception of helium, undergo a phase transition to the solid phase. This behavior is illustrated in Fig. 2, where we show a typical pressure–temperature phase diagram. In the figure we also draw the pressure–temperature line characterizing the BEC phase transition of an ideal gas. Above this line, a dilute gas would be Bose–Einstein condensed. However, this configuration is unstable since thermodynamic equilibrium would correspond to the solid

Fig. 1 Schematics of the level occupancy for a harmonically trapped gas at ultralow temperature. The ground state of the many-body system is completely determined by the quantum statistics. At zero temperature bosons (even-spin particles) all occupy the same single-particle ground state, forming a Bose–Einstein condensate. Fermions (odd-spin particles), obeying the Pauli exclusion principle, pile up until they reach the Fermi energy E_F .

Fig. 2 A typical pressure–temperature phase diagram. The *dashed line* corresponds to the BEC phase transition for an ideal gas.

phase for such values of pressure and temperature. This shows that BEC can be actually achieved only in conditions of metastability and that the density of the gas should be small enough in order to suppress the collisional processes (three-body collisions) responsible for bringing the system into the thermodynamically stable solid phase. In practice, typical densities reached in the BEC phase are $10^{13} - 10^{15} \text{ cm}^{-3}$, so the predicted values of T_c are extremely low (a few microKelvin or even less). This explains why Bose–Einstein condensation was experimentally realized in atomic gases only seventy years after Einstein’s historical paper.

Bose–Einstein condensation was achieved for the first time in ultracold gases of alkali atoms in 1995 and was recognized with the Nobel Prize for Physics in 2001 to E. A. Cornell, W. Ketterle, and C. E. Wieman (Cornell and Wieman, 2002; Ketterle, 2002). This achievement is the result of extraordinary efforts made in atomic physics during the two last decades of 1900s (Inguscio and Fallani, 2013; Inguscio et al., 1999), through the development of advanced techniques of laser cooling and atom trapping, which were recognized with the award of the Nobel Prize for Physics in 1997. At present BEC has been achieved in atomic gases made by isotopes of a variety of different chemical elements: alkali atoms (Li, Na, K, Rb, and Cs), alkaline-earth atoms (Ca and Sr) and other two-electron atoms (Yb) including metastable Helium (He^*), inner-shell transition metals and lanthanide atoms (Cr, Dy, and Er), and in atomic hydrogen (H) as well.

How to reach BEC in dilute atomic gases

The first experimental studies on BEC were focused on spin-polarized hydrogen, which was considered the most natural candidate because of its light mass, which naturally leads to a more pronounced quantum behavior (see Eq. 1). To this purpose cryogenic and evaporative cooling techniques were developed since the early 1970s. Eventually, BEC was first realized in alkali atoms, despite their relatively large masses, because of their suitability to be cooled with laser techniques.

Indeed, all the experimental realization of BECs in atomic gases (except hydrogen) do involve some form of laser cooling, where the radiation pressure force, arising from the exchange of momentum between the photons of a laser field and the atoms, is used to reduce the atomic velocity (Inguscio and Fallani, 2013; Inguscio et al., 1999). The most common configuration is that of a magneto-optical trap (MOT), where three pairs of orthogonal, counterpropagating laser beams, red-detuned with respect to an atomic transition, result in a viscous force (also called “optical molasses”) slowing the motion of the atoms. In addition, the presence of a magnetic field gradient allows the atoms to be spatially confined around the point where the magnetic field vanishes. In the case of rubidium, one can typically trap $\sim 10^9$ atoms with a temperature of $\sim 10 \text{ } \mu\text{K}$ in a region of $\sim 1 \text{ cm}^3$.

The density and temperature achievable in a MOT are far from the values required for Bose–Einstein condensation, mostly because of laser-induced collisions between the atoms, which limit the maximum density achievable in a MOT. The next stage consists in transferring the laser-cooled sample from the MOT to a conservative trap, either a magnetic trap or an optical dipole trap, as shown in Fig. 3. In both the cases the trapping potential arises from the interaction of an atomic dipole moment with a spatially varying field: magnetic traps are based on the Zeeman interaction $-\boldsymbol{\mu} \cdot \mathbf{B}(\mathbf{r})$ between the magnetic dipole moment $\boldsymbol{\mu}$ (proportional to the angular momentum of the atom) and an inhomogeneous magnetic field $\mathbf{B}(\mathbf{r})$; optical dipole traps are based on the optical dipole potential $-\mathbf{d} \cdot \mathbf{E}(\mathbf{r})$ which arises when a far-detuned laser field with electric field amplitude $\mathbf{E}(\mathbf{r})$ induces an electric dipole

Fig. 3 Atom trapping. In a magnetic trap the atoms are trapped in a local minimum of the magnetic field $B(\mathbf{r})$ created by sets of electromagnets. In an optical dipole trap the atoms are trapped in local minima or maxima of the laser intensity $I(\mathbf{r}) \propto |E(\mathbf{r})|^2$ (maxima, for red-detuned optical traps).

moment $\mathbf{d}$ (proportional to the electric field) in the atom. In both the cases the atoms are trapped in a local minimum of the confining potential, corresponding to a magnetic field minimum for magnetic traps or to a minimum/maximum of light intensity (according to the sign of the laser detuning) for optical dipole traps.

Despite the intrinsic robustness of magnetic traps (typically created with arrangements of electromagnets), optical dipole traps have become increasingly popular over the last 20 years, as they allow for a much larger variety of trapping potentials. Exploiting the interference between counterpropagating laser beams, it is possible to produce for example, *optical lattices*, that is, periodic arrays of microscopic optical dipole traps corresponding to the antinodes of the laser standing wave (see Section “Further directions”). Furthermore, by shaping the trapping laser with spatial light modulators, it is possible to create almost any trapping configuration, including “box-like potentials” where BEC in a uniform gas can be studied.

The final cooling stage is the so called *evaporative cooling*, that consists in the selective removal of the most energetic atoms from the trap. This process, allowing a reduction of the average energy per atom, can be accomplished either by using frequency-selective radiofrequency/microwave transitions toward spin states that are untrapped by magnetic traps, or by lowering the trap depth in optical dipole traps. If this forced evaporation is slow enough the remaining atoms have time to collide and restore a thermodynamic equilibrium at lower temperatures. At the end of this process, if the density of the sample is high enough, the phase transition to a Bose–Einstein condensate can take place (typical values for rubidium are $n \sim 10^{14} \text{ cm}^{-3}$ and $T \sim 100 \text{ nK}$). Bose–Einstein condensation in a trap occurs both in momentum and coordinate space, with the atomic density distribution reflecting the shape of the trapping potential.

All these cooling stages are performed in a ultra-high-vacuum environment (typical background pressure $\sim 10^{-11}$ torr), in order to ensure an optimal thermal isolation and a long lifetime (~ 1 min) of the trapped atomic samples against collisions with the room-temperature background gas.

Imaging the new macroscopic quantum state

Images of the ultracold atomic sample can be obtained by shining a resonant laser beam. The absorption of light by the atoms creates a shadow that is recorded by a CCD camera. The typical size of a condensate is of the order of a few micrometers and a very high resolving power is hence necessary for *in situ* imaging. Most frequently, images are taken by switching the trap off and allowing the gas to expand to larger sizes. Typical images obtained after expansion are shown in Fig. 4. At temperatures higher than T_c (left), the sample expands ballistically and quickly reaches an isotropic distribution, well described by a Maxwellian distribution, from which the temperature of the gas can be measured. At the onset of the BEC transition (center), the shape of the cloud is characterized by a pronounced increase of the density in the center and by a characteristic bimodal distribution: the non condensed atoms determine the wings of the distribution, still given by a Maxwellian form, while the condensed atoms give rise to a narrow central peak, which becomes more and more pronounced as the temperature is lowered (right). The shape of the central peak is no longer a

Fig. 4 (Top) Absorption images of an expanded cloud of ^{87}Rb bosons recorded at LENS by varying the temperature T across the BEC transition at T_c . From left to right, the images show a thermal cloud, a partially condensed cloud and a pure BEC. (Bottom) Cross sections of the density distributions. The lines are fits of the experimental points with a gaussian, a bimodal distribution and an inverted parabola, respectively.

(B) BEC density profile: circles are experimental results from Harvard University while the dashed line is the theoretical prediction for a noninteracting BEC. Reproduced from Ensher JR, Jin DS, Matthews MR, Wieman CE, and Cornell EA (1996) Bose-Einstein condensation in a dilute gas: Measurement of energy and ground-state occupation. *Physical Review Letters* 77: 4984 and Hau LV, Busch BD, Liu C, Dutton Z, Burns MM, and Golovchenko JA (1998) Near-resonant spatial images of confined Bose-Einstein condensates in a 4-Dee magnetic bottle. *Physical Review A* 58: R54 with permission from the authors.

Maxwellian and depends on the properties of the confining potential: in the most common experimental realization, the trap can be approximated as harmonic and the shape of the condensate is an inverted parabola, as predicted by the Gross–Pitaevskii theory (see Section “Role of interactions”). The analysis of the images also provides the number N of atoms in the sample and the condensed fraction.

In the presence of harmonic confinement, theory predicts precise values for both the critical temperature T_c and the fraction of condensed atoms for $T \leq T_c$. For an ideal gas trapped by a harmonic potential one finds (Dalfovo et al., 1999)

$$k_B T_c \simeq 0.94 \hbar \omega_0 N^{1/3} \quad (2)$$

and

$$\frac{N_0}{N} = 1 - \left(\frac{T}{T_c} \right)^3 \quad (3)$$

where ω_0 is the geometric average of the trapping frequencies and N_0 is the number of atoms in the condensate. One of the first theory–experiment comparisons (Ensher et al., 1996) is shown in Fig. 5A, where the value of T_c is a few hundreds of nanoKelvin. Despite the relatively small number of atoms used in this experiment ($\sim 10^4$) the evidence for the phase transition is very clear. The good agreement with the predictions of the ideal gas model indicates that the effects of atom–atom interactions on the condensate fraction and on the value of T_c are small. This is the consequence of the extreme diluteness of the trapped gas.

Role of interactions

Interactions between atoms play an important role in the experimental realization of ultracold atomic gases. Most importantly, they are responsible for the thermalization of the gas following the selective removal of the hottest atoms in evaporative cooling. As discussed in the previous section, this is a crucial step for the achievement of the low temperatures that are required for the realization of Bose–Einstein condensation.

Besides their importance in the cooling process, interactions play a crucial role in determining some of the equilibrium properties of the Bose–Einstein condensed gas (Dalfovo et al., 1999; Pethick and Smith, 2002; Pitaevskii and Stringari, 2016). For example, the size of the condensate, which, in the absence of interactions, is fixed by the harmonic-trap oscillator length, can become dozens of times larger as a consequence of the repulsion between atoms, as shown in Fig. 5B (Hau et al., 1998). Interactions also affect other dynamic properties, like the propagation of collective excitations and the expansion of the BEC after the removal of the confining potential. Both the equilibrium and the dynamic properties of interacting dilute Bose–Einstein condensed gases are well described by the Gross–Pitaevskii equation, which then provides the basic theoretical framework to describe several many-body features of these systems,

$$i\hbar \frac{\partial \psi}{\partial t} = \left(-\frac{\hbar^2}{2m} \nabla^2 + V(\mathbf{r}) + \frac{4\pi\hbar^2 a}{m} |\psi|^2 \right) \psi \quad (4)$$

where ψ is the BEC wavefunction and $V(\mathbf{r})$ is the external confining potential. The last term in parenthesis, leading to a nonlinear character of the equation, describes atom–atom interactions in a mean-field approximation. Remarkably, interactions in ultracold dilute gases are described by a single parameter a , which fixes the most relevant many-body properties of the system and whose sign characterizes the nature of the system in a unique way: when $a > 0$ interactions have a repulsive character, when $a < 0$ they are attractive. In the case of Bose gases $a \geq 0$ is required to ensure the stability of large Bose–Einstein condensed gases against collapse. When a becomes negative the nonlinearity in the Gross–Pitaevskii equation is also responsible for solitonic solutions (bright solitons) which propagate without dispersion in 1D configurations.

An exciting feature of ultracold-atom experiments is the possibility to control the scattering length by taking advantage of the so-called *Feshbach resonances* (see Fig. 6A). This phenomenon occurs when the energy of two colliding atoms in a given spin configuration (open channel) is quasiresonant with the energy of a molecular state that can be formed by those atoms in a different spin configuration (closed channel). The resonance condition can be controlled by tuning the energy separation $\Delta(B)$ between the two channels thanks to the differential Zeeman shift induced by an external magnetic field B . When the resonance condition is met, the scattering length exhibits a divergence and changes sign from one resonance side to the other, eventually crossing a point where it can be zeroed, as shown in Fig. 6B (Inouye et al., 1998). This magnetic tuning of the scattering length allows for unique possibilities in the physics of interacting ultracold gases, as described further in the next sections.

Fermi gases

Differently from the case of bosons, an ideal Fermi gas does not exhibit a phase transition at low temperature. The system, however, is still characterized by important quantum phenomena originating from the Pauli exclusion principle. This is well illustrated in Fig. 1, where one sees that at very low temperatures the gas exhibits single occupancy of the single-particle states up to a maximum energy, called *Fermi energy*.

The experimental procedure to reach quantum degeneracy in Fermi gases requires an additional effort compared to the case of bosons. As a matter of fact, in a Fermi gas of identical particles, the antisymmetrization requirement forbids s-wave collisions, which is the only collisional channel available at low temperature, and this causes the absence of those thermalization processes which are crucial for the mechanism of evaporative cooling. This difficulty can be overcome by cooling mixtures of fermions in two spin states, which are distinguishable and thus can interact also at low temperature. Alternatively, one can use mixtures of fermions and bosons, either of the same chemical species or of different species: bosons are cooled down with the standard evaporative cooling technique and then fermions thermalize sympathetically. Fig. 7 shows this second type of approach, achieved with mixtures of potassium and rubidium (Roati et al., 2002).

Despite the complication of the cooling procedure, the absence of interactions in a gas of spin-polarized fermions can provide important advantages. An example is given by the application of polarized Fermi gases to accurate measurements, that is, in atom interferometry, or in high-precision spectroscopy, where the absence of atom–atom interactions prevents unwanted decoherence effects or interactions shifts, respectively.

On the other side, the possibility of trapping fermions in different spin states has opened new perspectives related to the physics of interacting systems. In the first decade of 2000s, experimentalists were able to realize superfluid configurations in interacting Fermi gases, profiting of the possibility of tuning the interaction between pairs of atoms in different spin states in proximity of

Fig. 6 (A) A Feshbach resonance occurs when the energy of two colliding atoms (open channel) matches the energy of a molecular bound state for the same atoms in a different spin configuration (closed channel), and can be tuned by applying a magnetic field that shifts the two molecular potentials $V(R)$, where R is the interatomic distance. (B) First observation of a Feshbach resonance in a ^{23}Na Bose–Einstein condensate reported in 1998 at MIT. Reproduced from Inouye S, Andrews MR, Stenger J, Miesner H-J, Stamper-Kurn DM, and Ketterle W (1998) Observation of Feshbach resonances in a Bose–Einstein condensate. *Nature* 392: 151 with permission from the authors.

Fig. 7 Sympathetic cooling of fermionic ^{40}K with bosonic ^{87}Rb , as first reported at LENS in 2002. The bosons are directly cooled with standard evaporative cooling techniques and the fermions thermalize sympathetically at lower temperatures via collisions with the bosons. The figure shows the simultaneous onset of Fermi degeneracy for ^{40}K (left) and of Bose-Einstein condensation for ^{87}Rb (right). The absorption images are taken for decreasing temperatures (from top to bottom) and the sections show the correspondent momentum distributions. Figure reproduced from Roati G, Riboli F, Modugno G, and Inguscio M (2002) Fermi-Bose quantum degenerate 40K-87Rb mixture with attractive interaction. *Physical Review Letters* 89: 150403.

Feshbach resonances (see Inguscio et al. (2007) for a review of the first years of investigations). In the case of Fermi gases, thanks to the repulsive effect of the Fermi pressure, the system can support $a < 0$ values. At zero temperature, dilute Fermi gases interacting with small and negative scattering length exhibit a superfluid phase described by the traditional BCS theory, which was first developed to describe the phenomenon of superconductivity. If the scattering length becomes large or positive, new scenarios for fermionic superfluidity take place. In particular, by adjusting the scattering length from $a < 0$ to $a > 0$ across a Feshbach resonance, it is possible to produce ultracold molecules made by two fermions in different spin states. Since these molecules have a bosonic nature, being composed of an even number of fermions, they can undergo a phase transition to BEC, similar to that exhibited by a gas of bosonic atoms. Molecular BECs were first demonstrated in 2003 starting from ^6Li and ^{40}K fermionic atoms (see Fig. 8 for the realization of a molecular $^{40}\text{K}_2$ BEC reported in Greiner et al. (2003)).

Fig. 8 Bose-Einstein condensation of $^{40}\text{K}_2$ molecules, as reported in 2003 at JILA. The (bosonic) dimers are produced starting with quantum degenerate ^{40}K fermions in two spin states and sweeping the value of an applied magnetic field across a Feshbach resonance. (A) Absorption images of the molecular density distribution after expansion. When the initial temperature of the fermionic cloud is lowered across a critical value (from left to right) a narrow peak appears in the momentum distribution. Fig. 9 BEC–BCS crossover. (A) Changing the value of the scattering length a across a Feshbach resonance, a binary mixture of fermions in two spin states evolves from the condensation of tightly bound bosonic molecules (on the BEC side $a > 0$) to the formation of weakly bound Cooper pairs with a size much larger than the interparticle distance (on the BCS side $a < 0$). (B) Dependence of the critical temperature on the interaction parameter. (A): Reproduced from Inguscio M, Ketterle W, and Salomon C (eds.) (2007) *Ultracold fermi gases*. In: *Proceedings of the International School of Physics “Enrico Fermi”, Varenna (Italy)-Course CLXIV*. IOS Press (chapter by W. Ketterle and M. Zwierlein) with permission from the authors.

In the following years, important efforts led to the first experimental investigations of the BEC-BCS crossover (see Fig. 9A), which occurs by varying continuously the scattering length a across a Feshbach resonance from positive to negative values (Zwinger, 2014). In particular, at resonance, where the scattering length becomes much larger than the average distance between atoms, the system exhibits new challenging features and acquires a universal behavior which is independent from the actual value of the scattering length. This is the so called *unitary Fermi gas*, of special interest also in other domains of physics like in neutron matter and characterized by peculiar superfluid features. In particular, the value of the critical temperature at unitarity, characterizing the transition from the normal to the superfluid phase, is a significant fraction of the Fermi temperature (see Fig. 9B), much higher than in the case of the presently available high- T_c superconductors. The theoretical investigation of the unitary regime cannot be simply described using the theory of weakly interacting gases and requires the use of more advanced many-body approaches.

Coherence and superfluidity

Bose–Einstein condensates are characterized by a complex order parameter (the so called *wavefunction* of the condensate)

$$\Phi = \sqrt{n_0} e^{iS}. \quad (5)$$

The modulus is fixed by the condensate density n_0 , which, in dilute gases and at temperatures much smaller than T_c , practically coincides with the density of the sample. The phase S of the order parameter is at the origin of important properties of the system, both concerning coherence and superfluid effects.

Coherence phenomena make the physics of these systems similar to that of a laser, if one replaces photons with atoms. Indeed, the laser field can be described in terms of photons all occupying the same mode of the electromagnetic field, similarly to the atoms of a BEC all sharing the same wavefunction. Bright sources of atoms, the so called *atom lasers*, can be obtained outcoupling the atoms from the condensate, that is the analog of the laser cavity in which coherent photons are stored, with the eventual demonstration of atom lasers operating in continuous-wave mode (Chen et al., 2022). Another example of this analogy is revealed by the interference phenomena observed with Bose–Einstein condensates. In Fig. 10 we show the interference fringes produced by two separate condensates overlapping after expansion (Andrews et al., 1997). This experiment, which first demonstrated the coherence of the condensed state, is the analog of the most famous double slit experiment with light.

An important consequence of the complex order parameter and of the presence of interactions concerns the phenomenon of superfluidity. In fact the gradient of the phase S is proportional to the superfluid velocity:

$$\mathbf{v}_s = \frac{\hbar}{m} \nabla S \quad (6)$$

Before 1995, superfluid phenomena had been observed only in dense liquids, like ^4He . The possibility of investigating superfluidity in dilute gases has allowed a better understanding of its microscopic origin and its relationship to the phenomenon of BEC (Pitaevskii and Stringari, 2016). Among the various manifestations of superfluidity, it is worth mentioning the rich variety of collective oscillations exhibited by these confined systems, which have been the object of intense theoretical and experimental work in the last decades. The images in Fig. 11 show the shape oscillation of a Bose–Einstein condensate, from which one can extract the frequency of the collective modes with high precision. The dynamic behavior of the condensate is well described by the hydrodynamic equations of superfluids, which predict values for collective frequencies in excellent agreement with the experiment.

Fig. 10 Interference of two BECs overlapping after expansion. In the central region, one clearly sees interference fringes, similar to the ones observed in optics in the famous Young experiment. This image was recorded in 1997 at MIT in the first experiment where interference of two BECs was observed. Reproduced from Andrews MR, Townsend CG, Miesner HJ, Durfee DS, Kurn DM, and Ketterle W (1997) Observation of interference between two Bose condensates. *Science* 275: 637 with permission from the authors.

Fig. 11 Collective excitations of a Bose–Einstein condensate, as detected in early MIT experiments. The excitations were produced by modulating the magnetic field used to trap the condensate and then letting the cloud evolve freely. The field of view in the vertical direction is about $600\text{ }\mu\text{m}$ and the time step is 5 ms per frame. The measured frequency of these collective excitations is a clear signature of the BEC superfluidity. From D. Stamper-Kurn and W. Ketterle (private communication), reproduced from Dalfovo F, Giorgini S, Pitaevskii LP, and Stringari S (1999) Theory of Bose–Einstein condensation in trapped gases. *Reviews of Modern Physics* 71: 463.

An even more spectacular prediction of superfluidity concerns the rotational properties of ultracold atomic gases. Superfluids cannot rotate like classical objects because of the irrotationality constraint imposed by Eq. (6). A striking consequence is that angular momentum can be carried only by quantized vortices. If the confining trap rotates slowly, vortices cannot be formed because they are energetically unfavorable and the sample does not carry any angular momentum. However, when the angular velocity increases, quantized vortices are formed (see Fig. 12A). Eventually, at high angular velocities, one can generate a vortex lattice of regular geometrical shape. Quantized vortices have been observed also across the BCS–BEC crossover of an interacting Fermi gas, reflecting the universality of the superfluid behavior exhibited by interacting quantum gases (see Fig. 12B).

Another important manifestation of coherence is given by the Josephson oscillations characterized by the coherent tunnelling of atoms through the barriers generated by external double-well (Albiez et al., 2005) or many-well potentials (Cataliotti et al., 2001), as shown in Fig. 13. This peculiar effect is associated with an oscillating behavior of the relative phase between the two condensates occupying the wells and has been observed also through the interference patterns measured after expansion. The Josephson effect plays a crucial role also in the coherent oscillation between condensates in two different internal state (so-called *internal* Josephson effect), where all the atoms of the cloud oscillate in sync between the two states.

The Josephson effect was originally predicted for superconductors, where Cooper pairs can move by coherent tunnelling through a small insulating region. Recently, at LENS, such fascinating phenomenon has been studied in superfluid Fermi gases across the BEC–BCS crossover, allowing for the observation of effects beyond the perturbative BCS theory.

Collective modes of Josephson-like nature have been investigated also by exciting the center of mass oscillations of a BEC gas confined in the combined potential created with a harmonic trap and an optical lattice produced by laser fields. Fig. 13 (right) shows that only the superfluid condensed component is able to tunnel coherently while the thermal component is localized. Theoretically one can predict the frequency of the oscillation, which turns out to be in good agreement with the experiment.

Fig. 12 (A) Formation of vortices in a Bose–Einstein condensate, as observed in 2000 at LKB-ENS: as the rotation frequency of the trap increases (from left to right), a higher number of vortices is formed (Madison et al., 2000). (B) Vortex arrays in two-component strongly interacting Fermi gases, demonstrating a superfluid behavior all the way from the BCS to the BEC limit, as first observed in 2005 at MIT. Fig. 14 Propagation of sound modes in a fermionic ${}^6\text{Li}$ superfluid, as reported in 2013 at Innsbruck University. (A) A focused laser beam creates an excitation in a localized region of the superfluid. (B) Propagation of density waves (ordinary sound). (C) Propagation of entropy/temperature waves (second sound). The two sounds clearly propagate at a different speed. Reproduced from Sidorenkov LA, Tey MK, Grimm R, Hou Y-H, Pitaevskii L, and Stringari S (2013) Second sound and the superfluid fraction in a Fermi gas with resonant interactions. *Nature* 498: 78.

Important superfluid phenomena take place also at finite temperature, where Landau's theory predicts the occurrence of peculiar dynamic features described by two-fluid hydrodynamics. The most spectacular manifestation is the propagation of a new type of sound, the so-called *second sound*, that was extensively investigated in superfluid helium. Differently from usual sound, which corresponds to a pressure wave, second sound can be regarded as an entropy wave and the corresponding velocity is intimately related to the superfluid density of the system. Second sound was measured in a strongly interacting Fermi gas close to unitarity (Fig. 14) allowing for the first determination of the temperature dependence of the superfluid fraction of a Fermi superfluid (Sidorenkov et al., 2013). More recently, second sound was also measured in two-dimensional Bose gases.

Quantum mixtures of ultracold atomic gases

The possibility of reaching ultracold temperatures in both Bose and Fermi gases and in a variety of different atomic species has opened an exciting development of experimental and theoretical activities in the field of the so called *quantum mixtures*, where gases of different atomic species can co-exist and interact in the quantum degenerate limit, giving rise to novel phenomena (Grimm et al., 2023). This possibility was long sought in the past in the case of mixtures of liquid ${}^4\text{He}$ and ${}^3\text{He}$, where, however, the possibility of obtaining two interacting superfluids is inhibited by the lack of miscibility of the two helium fluids at very low temperature. New possibilities have now become available in the case of ultracold atomic gases, both with Bose–Bose and Bose–Fermi superfluid mixtures, including the interdisciplinary topic of *polarons*, which corresponds to extreme population unbalanced mixtures, where essentially only one or few impurities of a certain atomic species are immersed in a bath formed by the other component.

The studies of polarons in a clean ultracold-gases setup has already allowed for a better understanding and direct measurement of the concept of dressed particles by the bath excitations, as well as the back action of the impurities on the bath itself.

The phenomenology specific of a certain mixture is very rich and very diverse depending on the “ingredients” of the selected mixture. In particular for Bose mixtures, one can distinguish between mixtures where the number of atoms of each species is conserved and those in which only the total number of atoms is conserved. To the first class belong mixtures of different atomic species while the second class concerns mixtures of hyperfine levels where, due to either spin-changing collisions or external fields, the number conservation of the single components is broken.

Among the most interesting effects in mixtures we can count the existence of a collisionless drag between the two superfluid components and, even more remarkably, of self-bound droplets and of a liquid-like (incompressible) phase. The description of the above-mentioned phenomena is not included in a simple two-component Gross–Pitaevskii equation and requires the inclusion of the so-called quantum fluctuations.

For non-number-conserving mixtures, it is remarkable the presence of magnetic-like quantum phase transitions (i.e., phase transitions that occur at zero temperature), where the magnetic language is used to describe the spinor or vector order parameter of the system. It is therefore possible to study magnetic superfluids and the interplay between superfluidity and magnetism. In the same framework, it was possible to realize condensates with spin–orbit coupling, allowing for new states of matter, complementary to the electronic states in solid-state physics.

Further directions

The possibility of tuning the interactions among atoms and the large variety of trapping conditions reachable by combining magnetic and optical methods has allowed for the realization of a number of configurations involving Bose and/or Fermi gases (see Bloch et al. (2008) and Inguscio et al. (2016) for a review of major developments). The resulting scenarios are still evolving and cover topics of high interdisciplinary interest, as briefly listed below.

Optical lattices

Optical lattices can be used to provide perfect periodic potentials where the atoms can be trapped, in very close analogy to what happens in the solid state, where the electrons are bound to the periodic arrangement of atoms of the crystalline structure.

Since the first years of this century, optical lattices have been used as a powerful instrument to probe the coherence and superfluid properties of Bose–Einstein condensates: notable examples are the observation of many-BEC interference with long-range coherence or the realization of Josephson junctions arrays (Cataliotti et al., 2001). Optical lattices are also an ideal tool to study key aspects of quantum transport in defect-free solid-state analogs, such as the modification of the transport properties caused by the emerging band structure (Fallani et al., 2003), according to Bloch theorem (Fig. 15A). Fundamental effects of solid-state physics were cleanly observed in this setting, the most prominent one being the occurrence of undamped Bloch oscillations activated by a constant force (Fig. 15B), which are also a valuable resource for precision measurements in the context of atom interferometry (Roati et al., 2004).

This analogy with the solid state has been exploited intensively to provide the first realizations of the idea of *quantum simulation* pioneered by R. Feynman in the 1980s. Optical lattices were used to provide a clean realization of bosonic and fermionic Hubbard models, originally introduced in condensed-matter physics to describe interacting quantum particles hopping between the sites of a deep lattice. By an accurate experimental control of the coupling constants of the Bose–Hubbard model, a quantum phase transition between a superfluid state and a Mott insulator was observed (Greiner et al., 2002), as shown in Fig. 16: when the depth of the optical lattice is small, interactions effects are weak and the system exhibits long-range coherence, which is witnessed by the sharp peaks in the matter-wave interference; when the lattice depth is increased above a critical value, repulsive interactions between particles dominate over the hopping and the system localizes in a Mott state with no particle number fluctuations and no coherence, and the peaks in the matter-wave interference disappear. Experimental studies of the Fermi–Hubbard model have also evidenced the antiferromagnetic ordering of the Mott localized phase for a mixture of spin-up/spin-down fermions, which is believed to provide a key mechanism for the explanation of high-T_c superconductivity in cuprates, also opening new paths for the exploration of spin lattice models.

Disorder

Not only light can be used to create optical lattices where solid-state models can be simulated in a defect-free way. It can also be used to realize controllable disordered or quasi-disordered potentials, via the use of speckle patterns or multichromatic optical lattices, respectively. In this settings, Anderson localization of matter waves was first observed by studying the expansion of a Bose–Einstein condensate in a disordered potential (Billy et al., 2008; Roati et al., 2008): when the amount of disorder was strong enough, the BEC stopped its free expansion in the disordered potential, in correspondence with the transition of the eigenstates from extended to localized (see Fig. 17). Since the first observations of localization in disordered BECs, the interplay between disorder and interactions has been studied extensively, also in the context of the topic of many-body localization, where localization is accompanied by nontrivial quantum effects concerning thermodynamics and equilibrium.

Fig. 15 Quantum transport in an optical lattice, as studied in early experiments at LENS: (A) Experimental measurements of the velocity and effective mass of a BEC in an optical lattice as a function of its quasimomentum, compared with the predictions of the Bloch theory describing electrons in a crystal lattice. (B) Ultracold fermions trapped in a vertical optical lattice, performing long-lived Bloch oscillations under the effect of gravity: measuring the frequency of the oscillation allows an accurate determination of the local gravity acceleration g and can be used for high-precision measurements of forces on a short distance scale. Fig. 16 Quantum phase transition from a superfluid to a Mott insulator for ultracold bosons in a 3D optical lattice, as first observed in 2002 at MPQ. In the Mott phase, the atoms are localized in the lattice sites, phase fluctuations increase and the long-range coherence of the superfluid phase is lost. This is evidenced by the disappearance of the matter-wave interference pattern when the lattice depth is increased (from A to H). Reproduced from Greiner M, Mandel O, Esslinger T, Hänsch TW, and Bloch I (2002) Quantum phase transition from a superfluid to a Mott insulator in a gas of ultracold atoms. *Nature* 415: 39 with permission from the authors.

Synthetic fields and synthetic matter

Starting from the 2010s new experimental approaches involving the manipulation of BECs with laser light have allowed researchers to engineer new kind of interactions for quantum simulation experiments. Pioneering experiments performed at JQI/NIST demonstrated the possibility of realizing light-induced spin-orbit interactions, by which the motion of the atoms is coupled to their spin, or synthetic magnetic fields, in which the phase imprinted by the interaction with the lasers emulates a magnetic vector potential, thus mimicking the effect of a synthetic magnetic field on atoms with a synthetic charge (see [Goldman et al. \(2014\)](#) for a review). These first demonstrations triggered a new field of research, in which BECs and Fermi gases are used to study novel quantum phases and topological states of matter.

Fig. 17 Evidences of Anderson localization with ultracold atoms, as first reported in 2008 at Institut d’Optique and LENS. (A) The wavefunction of a weakly interacting ^{87}Rb BEC expanding in a speckle potential shows exponentially decreasing tails. (B) The momentum distribution $|\tilde{\Psi}(p)|^2$ of a noninteracting ^{39}K BEC in an incommensurate bichromatic lattice becomes broad as the wavefunction $\Psi(x)$ changes from extended to Anderson-localized when the amplitude of the quasidisorder is above a localization threshold. Reproduced from Billy J, Josse V, Zuo Z, Bernard A, Hambrecht B, Lugan P, Clément D, Sanchez-Palencia L, Bouyer P, and Aspect A (2008) Direct observation of Anderson localization of matter waves in a controlled disorder. *Nature* 453: 891 and Roati G, D’Errico C, Fallani L, Fattori M, Fort C, Zaccanti M, Modugno G, Modugno M, and Inguscio M (2008) Anderson localization of a noninteracting Bose-Einstein condensate. *Nature* 453: 895. with permission from the authors.

Low-dimensional physics

Since the first realizations of optical lattices, it was clear that the strong confinement of the atoms in the lattice sites also represented a practical tool to study BEC in low-dimensional settings. As a matter of fact, a strong 1D optical lattice can be used to restrict the atomic motion on a 2D plane while a strong 2D lattice can create quantum wires, where the motion of the atoms is restricted along 1D only. The dimensionality of space has important consequences on the collective properties of many-body quantum systems, with dramatic effects that emerge from the interplay of interactions and reduced dimensionality. In an interacting 2D Bose gas superfluidity can arise even in the absence of Bose–Einstein condensation, as a result of a Berezinskii–Kosterlitz–Thouless (BKT) transition. The collective excitations of an interacting 1D Bose gas can be described in terms of the theory of Luttinger liquids and the system can even realize a “fermionized” Tonks–Girardeau gas, where the strong repulsion between the bosons force them to acquire a fermionic behavior, playing the role of an effective Pauli repulsion.

Long-range interactions

The vast majority of experimental and theoretical works on ultracold gases deals with atoms whose interaction—at the energy and temperatures of interest—can be described as contact-like and described by s -wave scattering lengths. More recently it has been possible to trap and manipulate gases where the dipolar interaction is strong enough to give rise to new phenomena, due to its long-range and anisotropic nature. A first approach to make the dipolar interaction relevant for the phenomenology of the system is to consider atoms with a relatively large dipolar interaction, as rare-earth atoms, and reduce the strength of the contact interaction by exploiting Feshbach resonances. In this way physicists were able to obtain the quantum equivalent of ferrofluids, to measure roton-like spectra, and, for Fermi gases, to characterize Fermi sphere deformations, just to mention a few. In particular it was observed that, when the dipolar interaction becomes large enough, the gas can break into a matrix of self-bound droplets (Kadau et al., 2016), as shown in Fig. 18. The nature of these droplets is very similar to that of the droplets found in Bose–Bose mixtures, since they are both stabilized by quantum fluctuations. Even more importantly, such droplets can be made coherent among each other, allowing for the very first observation of the so-called supersolid state (see below).

Magnetic dipolar atomic gases are not the only platforms where long-range interaction can play a major role in the context of ultracold gases. Another possibility is to exploit the electric dipole moment of heteronuclear binary molecules. In this case the dipole–dipole interaction can be very strong and much attention has been devoted to long-range interaction effects in molecular gases loaded in deep optical lattices, with the realization of important solid-state Hamiltonians. Other approaches to synthesize effective long-range interactions include atoms in optical cavities, Rydberg atoms, and trapped ions. The latter platforms are considered to be good candidates also for the realization of atom-based quantum computers.

Supersolidity

In the last few years supersolidity has emerged as an exciting and active frontier of research in the field of ultracold atoms. Supersolidity is an intriguing phenomenon, where both superfluid and crystalline properties coexist as a consequence of the simultaneous breaking of phase and translational symmetry. After unsuccessful attempts in solid helium, supersolidity was

Fig. 18 Observation of self-bound quantum droplets in a dipolar gas of ^{164}Dy , as observed in 2016 at University of Stuttgart. Reproduced from Kadau H, Schmitt M, Wenzel M, Wink C, Maier T, Ferrier-Barbut I, and Pfau T (2016) Observing the Rosensweig instability of a quantum ferrofluid. *Nature* 530: 194 with permission from the authors.

experimentally reported in 2017 in Bose–Einstein condensates with spin–orbit coupling (MIT) and inside optical resonators (ETH). Remarkably, in 2019 the supersolid state was realized in dipolar Bose gases almost at the same time in three different laboratories (at LENS-Pisa, Innsbruck and Stuttgart). The experimental and the theoretical research activity has then become particularly rich (see [Recati and Stringari \(2023\)](#)) for a review). In particular in the case of dipolar gases, phase coherence, the spatial modulations of the density profile, and the superfluid rotational properties, as well as the emergence of the Goldstone modes associated with the superfluid and crystal behavior, were observed.

Conclusion

The experimental realization of Bose–Einstein condensation in ultracold atomic gases in 1995 opened completely new research directions that were inconceivable before then. BEC experiments have become “quantum laboratories,” where quantum theories can be tested for the first time “on demand,” providing a natural embodiment of the “quantum simulation” approach envisioned by R. Feynman. Almost three decades of exciting research have led us to a much better understanding of fundamental physical effects, in a continuous synergy between theoretical studies and experimental investigations, always going hand-in-hand, one prompting each other in a virtuous circle. What could the developments of the next three decades be? In the last chapter we have identified some of the major trending topics, but the list is far from conclusive and it is difficult to foresee what the next breakthroughs will be. What we can certainly say is that a growing, enthusiastic community of scientists will keep working, trying to achieve a better understanding of the quantum world, also with the aim of translating this knowledge into new quantum-based technologies for the benefit of society at large.

Abstract

The emergence of macroscopic coherence in a many-body quantum system is a ubiquitous phenomenon across different physical systems and scales. This chapter reviews key concepts characterizing such systems (correlation functions, condensation, and quasi-condensation) and applies them to the study of emerging nonequilibrium features in the dynamical path toward such a highly coherent state: particular emphasis is placed on emerging universal features in the dynamics of conservative and open quantum systems, their equilibrium or nonequilibrium nature, and the extent that these can be observed in current experiments with quantum gases. Characteristic examples include symmetry-breaking in the Kibble–Zurek mechanism, coarsening and phase-ordering kinetics, and universal spatiotemporal scalings around nonthermal fixed points and in the context of the Kardar–Parisi–Zhang equation; the chapter concludes with a brief review of the potential relevance of some of these concepts in modeling the large-scale distribution of dark matter in the universe.

Key points

- Demonstration of ubiquitous nature of Bose–Einstein condensation and key observables characterizing it.
- Unified overview of the dynamical phase transition crossing from an incoherent initial condition to a (highly/fully) coherent final state, introducing key universal scaling laws applicable during such process.
- Detailed explanation of the Kibble–Zurek mechanism for a driven dynamical phase transition crossing through an external time-dependent parameter.
- Discussion of phase-ordering process and universal scaling at late evolution times following an instantaneous quench from an incoherent state.
- Applications of above frameworks to the dynamics of ultracold atoms and exciton-polaritons, with concrete examples and experimental observations.

- Discussion of other highly nonequilibrium features of quantum gases originally stemming from cosmology (nonthermal fixed points) and classical systems (Kardar–Parisi–Zhang).
- Review of cosmological condensation model for dark matter, and its analogies to laboratory condensates.

Introduction

Bose–Einstein condensation (BEC), first predicted nearly 100 years ago, is a phenomenon associated with the emergence of a highly coherent state which manifests itself across vastly different physical systems: Interestingly, not only the existence of the effect but also the manner in which it emerges dynamically across such systems can exhibit the same characteristic features (Proukakis et al., 2017). This chapter reviews such universality of the existence and the dynamical emergence of a Bose–Einstein condensate starting from an incoherent (or thermal) state: in particular, attention is paid to universal scaling laws and (dynamical) self-similarity associated with the initial growth stages when the system breaks the Hamiltonian symmetry to randomly choose phase domains in a potentially “turbulent” manner, and with the subsequent relaxation of such a nonequilibrium state to the corresponding final equilibrium state (or steady state). The main aim of this chapter is to give an overview of key concepts of (selected) universal scaling laws which have developed over decades across distinct branches of physics, and focus on those with recent applications to experimentally controlled quantum gases; as such, this chapter is only intended to give a “flavor” and not a thorough overview of such topics across other systems, for which the reader is referred to suitable review articles. Nonetheless, before concluding, I also briefly discuss a less widely known emerging new example characterizing the interplay between condensed matter physics, nonequilibrium statistical physics and cosmology/high-energy physics, in the context of how quasi-condensation, BEC and turbulence, characterized through relevant correlation functions, could potentially relate to our understanding of large-scale cosmological structures.

“Universality” of Bose–Einstein condensation

BEC is a fundamental manifestation of many-particle coherence in a quantum system, occurring when a system of many particles acquires wave-like properties. Such behavior emerges when the de Broglie wavelength $\lambda \sim h/p$ (where h is Planck’s constant and p is momentum) of the underlying particles becomes comparable to, or exceeds, the typical interparticle separation in the medium (Fig. 1). The textbook discussion of this effect (Huang, 1987; Dalfovo et al., 1999; Pitaevskii and Stringari, 2016; Pethick and Smith, 2002; Ueda, 2010) typically focusses on the case of a three-dimensional (3D) system of bosonic particles (i.e., particles of integer spin obeying Bose–Einstein statistics), for which such condensation emerges when the dimensionless phase-space density $n\lambda^3 \gtrsim O(1)$ (where $n = N/V$ is the number density of particles in the system) exceeds a value of order 1 (in a 3D noninteracting system, the exact value is $\zeta(3/2) \approx 2.612$). This occurs at a characteristic, or critical, value (ϵ_c) of the relevant external parameter, ϵ , which varies across, and thus induces, the transition. For example, in the well-studied case of particles being cooled (and noting that for such systems $\lambda \sim (mT)^{-1/2}$), BEC emerges at a critical temperature, T_c —a well-known characteristic in superfluidity/condensation phase diagrams of liquid helium and ultracold quantum gases.

Fig. 1 Schematic of the transition from a system of incoherent, distinguishable (potentially composite) bosonic particles having a mean interparticle distance $D \sim n^{-1/3}$ (left), through the critical region in which the de Broglie wavelength, λ , becomes comparable to D (when $n\lambda^3 \sim 1$) (middle), to the quantum-degenerate (highly coherent) regime in which the typical wavelength much exceeds the mean interparticle distance (right) in terms of an external control parameter ϵ (e.g., corresponding to decreasing system temperature). Depicted arrows indicate particle velocities, which typically start aligning in the transition region (when the external control parameter, ϵ acquires a critical value ϵ_c , which is typically set to zero for convenience) eventually forming a coherent matter wave, known as a Bose–Einstein condensate, with a unique (randomly chosen) direction; the reduced vector magnitudes shown here indicate cooling.

However, in general, the role of the critical external control parameter could be played by many different physical variables (Snoko et al., 2017): for example, for the systems considered in this chapter, beyond a critical temperature or a critical density, such a phenomenon could also arise in terms of a critical interaction—whose magnitude can also be controlled by the system confinement/dimensionality—or a critical pumping rate, although more broadly a system could be induced to criticality through a critical magnetic field or pressure.

The bosonic particle undergoing such change of state can be fundamental (e.g., photons (Klaers et al., 2010)), or composite—noting that an even number of fermions also acquires integer spin, thus behaving bosonically. The simplest example of a composite bosonic particle is that of a Hydrogen ^1H atom, which comprises two fermions: a proton in the core, surrounded by a single electron. As it turns out, significant success in laser cooling and trapping (Chu, 1998; Cohen-Tannoudji, 1998; Phillips, 1998) has facilitated BEC to be achieved in a range of dilute (and thus typically weakly interacting) alkali gases (Cornell and Wieman, 2002; Ketterle, 2002): in fact the first observations of a *weakly interacting* BEC across any physical system were made in ultracold atomic gases of ^{87}Rb and ^{23}Na (prior to its observation in spin-polarized ^1H , which followed a few years later (Fried et al., 1998; Greytak and Kleppner, 2017)). Helium is the first known superfluid (and the only one known to exist in thermodynamic equilibrium). Although the well-studied bosonic ^4He , which is also a composite boson, exhibits a clear transition at some characteristic temperature and reaches 100% superfluidity at $T = 0$, the fraction of condensed particles in such a system nonetheless remains under 10% due to the relatively strong atomic interactions. Composite bosonic quasiparticles can also be formed from an even number of fermions: the most striking example is that of electron-hole Cooper pairs in superconductors or pairs of fermionic ^3He atoms exhibiting superfluidity. Although the detailed microscopic mechanism here is different (the well-known Bardeen–Cooper–Schrieffer, or BCS, mechanism (Cooper and Feldman, 2010)), ultimately the composite bosonic quasiparticle still effectively undergoes a BEC-type transition to a state of macroscopic coherence (Leggett, 2006). In fact, the exquisite controlled setting of ultracold atomic gases enables one to probe, even experimentally, the transition from a BEC to a BCS coherent system (Zwinger, 2011). Another example receiving significant current attention over the past 15 years is the condensation of a composite half-matter-half-light quasiparticle known as an exciton-polariton condensate, which manifests itself in pumped semiconductor microcavities (Sanvitto and Timofeev, 2012; Deng et al., 2010; Carusotto and Ciuti, 2013).

Signatures of BEC (and macroscopic coherence in general) in fact arise across an immensely broad range of length and energy/temperature scales (see Fig. 2), spanning from nuclear and atomic physics, through optical and condensed matter systems to astrophysical (neutron star cores) and even cosmological (fuzzy dark matter) settings (Proukakis and Burnett, 2013)—a more extended discussion on such diverse manifestations can be found in Proukakis et al. (2017).

Although BEC was initially discussed in the context of a homogeneous, noninteracting 3D system, realistic systems are in fact of finite size and do exhibit some interactions—which can mask the effects of BEC, as in the case of superfluid ^4He . This led to a many-decade-long search for experimentally controllable weakly interacting systems which could exhibit BEC: ultracold atomic experiments have provided a natural setting for achieving and observing nearly pure condensates, despite their (typically) inhomogeneous nature and finite system size. Current experiments in such systems in fact facilitate a detailed understanding of the modifications to both equilibrium coherence properties and dynamical formation induced by inhomogeneous/trapped and finite-size configurations, the influence of (realistic) weak interactions, the transition to more strongly interacting settings, and the confinement to lower effective dimensionalities, alongside studies of mixtures, superfluid turbulence, quantum phase transitions and even long-range interactions and supersolidity. Moreover, the last 2 decades have facilitated another well-controlled system, namely that of exciton-polaritons, which additionally offer glimpses to nonequilibrium phase transition features.

Beyond a classification of equilibrium properties of such systems, a fascinating generic underlying question with a history of significant contributions spanning many decades and across diverse physical settings concerns the fundamental question of how such systems form, and what common—or universal—features may exist during such a process.

In this chapter, I discuss in a broad sense the main aspects of the dynamical path toward such a highly coherent state, focusing primarily on the context of trapped ultracold (bosonic) atomic gases, with some emphasis on realistic inhomogeneous settings that facilitate direct links to controlled experiments: applicability and extension of such concepts to other physical settings and systems—most notably exciton-polariton condensates—are also discussed at relevant points within this chapter. The presentation is kept at a broad introductory level, geared to a nonexpert audience, with the intention to give a flavor of such rich questions—for a more complete picture, and historical overview, the reader is referred to a number of excellent reviews on such topics (Proukakis et al., 2017; del Campo and Zurek, 2014; del Campo et al., 2013; Bray, 1994; Rutenberg and Bray, 1995a; Schmied et al., 2019; Chantesana et al., 2019; Jos, 2013; Bloch et al., 2022).

This chapter is structured as follows: The rest of Section “Introduction” gives a unified qualitative overview of the dynamical stages in the transition process from an initial incoherent state to the emerging final equilibrium or steady-state of the system (Section “Dynamical phase transition stages”), discussing the key physical quantities used to characterize such a system (Section “Relevant coherence measures”), with a brief introduction to the basic phenomenological description of a BEC (Section “Workhorse model of Bose–Einstein condensation”). Section “Universality during phase transition crossing: The Kibble–Zurek scaling law,” which forms the core of this chapter, addresses how coherence grows dynamically during an external parameter quench through spontaneous symmetry breaking and defect formation in the context of the so-called Kibble–Zurek mechanism giving rise to universal scaling laws: after giving a brief historical introduction (Section “Early ideas”) and presenting a minimal numerical model capturing such effects (Section “Numerical phase transition model”), the key underlying principles and scaling law of Kibble–Zurek are described mathematically by extending the ideas of equilibrium criticality (which are thus also briefly reviewed here in Section “Criticality at equilibrium”) to dynamical transition crossing (Section “Criticality in a dynamical setting” and

Elementary Boson	System	Density	Temp (K)

Quantum Gases: Finite Temperature and Non-Equilibrium Dynamics: 1 (Cold Atoms), London: Imperial College Press

“The Kibble–Zurek scaling law”) and then applying them to recent experiments (Section “Analyzing Kibble–Zurek in an elongated ultracold atomic system”) which highlight the need for a more extended framework to account for inhomogeneous systems and their interplay with causality, which is also presented here (Section “Beyond homogeneous Kibble–Zurek considerations”). Section “[Universality during phase-ordering dynamics](#)” discusses universal phase-ordering dynamics following an instantaneous quench, demonstrating the emergence of universal scaling of the spatial correlation function in characteristic late-time evolution stages of a relaxing quantum gas (Section “Scaling hypothesis and late-time coarsening”), with particular emphasis on highly nonequilibrium quenches giving rise to “turbulent” states evolving in the vicinity of nonthermal fixed points (Section “Evolution around nonthermal fixed points”). Section “[Selected further considerations](#)” presents a highly-relevant (but heuristic) selection of applications of such concepts to other systems, briefly mentioning for completeness other effects and manifestations in ultracold quantum gases not discussed here (Section “Beyond continuous single-component atomic gases”). Section “Driven-dissipative condensation in exciton-polariton systems” focuses on the emergence of dynamical features discussed in Sections “[Universality during phase transition crossing: The Kibble–Zurek scaling law](#)” and “[Universality during phase-ordering dynamics](#)” and the related spatiotemporal scaling according to a (quantum) mapping of phase evolution in an open, driven-dissipative, quantum gas of exciton-

polaritons to the well-known (classical) Kardar–Parisi–Zhang equation characterizing interfacial growth. Section “Bose–Einstein condensation on astrophysical/cosmological scales?” discusses the potential relevance of some of the discussed characterizations to the context of a cosmological-scale BEC, which is shown to exhibit many characteristics similar to harmonically confined ultracold quantum gases. General concluding remarks and outlook are given in Section “Conclusion.”

Dynamical phase transition stages

Condensate formation is a fundamental nonequilibrium problem with a very long history dating over many decades (see, e.g., selected influential early works (Kagan, 1995; Stoof, 1995, 1999), discussions (Gardiner et al., 1998; Bijlsma et al., 2000) of the first quantitative ultracold atomic growth experiments (Miesner et al., 1998; Köhl et al., 2002), and the review (Davis et al., 2017), which contains many more highly relevant references). The main question to be addressed here is how a system, originally in a disordered/incoherent state, transitions—through the breaking of a continuous symmetry—to an equilibrium state (or steady state) exhibiting a high degree of macroscopic coherence, the extent of which is set by the particular system under consideration (e.g., system geometry and dimensionality, nature and strength of interactions between constituent particles, mass of constituent boson). A schematic of the main steps during such a process is shown in Fig. 3 in terms of the external control parameter ϵ .

From an equilibrium perspective, such a transition can be visualized as a gradual passage through different equilibrium states, with a well-identified critical region (around $\epsilon \sim \epsilon_c \sim 0$) separating purely incoherent from emerging coherent states. But how is such a picture affected when the external control parameter is dynamically varied, that is, $\epsilon \rightarrow \epsilon(t)$? Let us consider here by means of an example the specific case of a temperature quench, for which $\epsilon = (T_c - T)/T_c$.

During the first stage of cooling, and while the system is still (sufficiently) above the critical temperature, particle dynamics can be described in the usual (classical) phase-space picture, based on a Boltzmann equation with collisions (Lifshitz and Pitaevskii, 1995). Under continuous cooling toward the critical point, particles are gradually redistributed into lower energy states (with elastic collisions typically occurring on a much faster timescale than that governing the variation of the external control parameter, thus providing the required thermalization).

The second, and arguably most interesting, stage in the evolution addresses the question of how the system dynamically crosses the phase transition, and what the nature of the nonequilibrium state generated in this vicinity of the critical point is. This is discussed in detail in Section “Universality during phase transition crossing: The Kibble–Zurek scaling law”: for now, it suffices to say that this leads to a delay in the crossing of the phase transition, and the emergence of interesting (potentially “chaotic,” or “turbulent-like”) nonequilibrium states displaying a (potential) abundance of phase defects and relevant universal properties: such emerging transient states depend, in general, on both the dimensionality/geometry of the system and the rate of crossing of the phase transition (e.g., adiabatically vs. instantaneously).

The final stage in the equilibration/thermalization of the system is intricately related to the subsequent relaxation of such phase defects, and the related emergence of (a certain degree of) macroscopic coherence across the system: universal behavior is again

Fig. 3 Dynamical phase transition schematic: As the external control parameter, ϵ , is dynamically varied across the transition (i.e., $\epsilon \rightarrow \epsilon(t)$), the system exhibits a delayed response compared to the corresponding equilibrium critical point at $\epsilon = \epsilon_c$ (corresponding, for example, to $T = T_c$), with ϵ_c typically set to 0, thus separating the incoherent ($\epsilon < 0$) from the coherent ($\epsilon > 0$) side of the phase transition. As soon as $\epsilon(t)$ dynamically crosses to a positive value, and still within the critical regime (i.e., $\epsilon(t) \rightarrow 0^+$), it acquires (in general) a chaotic, turbulent nonequilibrium configuration containing phase defects: such physics is dominated by a universal Kibble–Zurek scaling law governing the dynamical phase transition. The subsequent gradual relaxation of such defects leads to the emergence of macroscopic coherence over much longer timescales; this includes a self-similar “phase ordering” process obeying universal scaling laws. Other universal features discussed in this chapter (such as spatio-temporal evolution around nonthermal fixed points and Kardar–Parisi–Zhang scaling) may also appear at appropriate scales and evolutionary stages during the extended process, depending on the particular system, initial state preparation, and quenching protocol. Specific equilibrium density snapshots shown here sufficiently before/after the transition are for the specific cases of an elongated inhomogeneous 3D, and a homogeneous 2D, ultracold atomic gas—both analyzed within this chapter.

expected to emerge here in some dynamical scenarios/regimes (e.g., for homogeneous systems, or very rapidly quenched, highly nonequilibrium states), but the specific system details can potentially also leave their imprint on this process, thus masking (or even potentially modifying the details of) such universality.

Such discussion can be formulated in terms of two commonly considered types of quenched regimes: instantaneous quenches, where the system is prepared, or induced, into a highly nonequilibrium state, and finite-duration (i.e., noninstantaneous) quenches starting from an incoherent equilibrium configuration, in which the system is typically modeled on the basis of a smoothly varying external parameter inducing such transition. Both such cases lead to interesting universal physical laws, associated with the dynamical phase transition crossing and the subsequent phase-ordering process, as discussed in more detail below (Sections “Universality during phase transition crossing: The Kibble–Zurek scaling law” and “Universality during phase-ordering dynamics”), starting from the finite-duration phase transitions.

Relevant coherence measures

Classification of the system equilibrium and dynamical properties is intricately related to appropriate characterization of the degree of system coherence.

Correlation functions

For a quantum system described by Bose field operators $\hat{\Psi}(\mathbf{r}, t)$ and $\hat{\Psi}^\dagger(\mathbf{r}, t)$, a classification of the coherence in both the spatial and temporal domains can be obtained through the n^{th} -order correlation function

$$G^{(n)}(\mathbf{r}_1, \mathbf{r}'_1, \mathbf{r}_2, \mathbf{r}'_2, \dots, t_1, t'_1, t_2, t'_2, \dots) = \langle \hat{\Psi}^\dagger(\mathbf{r}_1, t_1) \hat{\Psi}^\dagger(\mathbf{r}_2, t_2) \dots \hat{\Psi}^\dagger(\mathbf{r}_n, t_n) \hat{\Psi}(\mathbf{r}'_n, t'_n) \dots \hat{\Psi}(\mathbf{r}'_2, t'_2) \hat{\Psi}(\mathbf{r}'_1, t'_1) \rangle \quad (1)$$

measured across n different spatial locations and at n different times (with $\dots$ intended to reflect remaining terms such that there are n pairs of $\hat{\Psi}^\dagger(\mathbf{r}_n, t_n) \hat{\Psi}(\mathbf{r}'_n, t'_n)$ contained within the above expectation value expression).

In practice, the most elementary—and thus most commonly discussed—correlation functions are those associated with spatial and temporal one-body correlations, respectively defined as

$$\text{Fixed } t: C(\mathbf{r}, \mathbf{r}') = C(\mathbf{r}, \mathbf{r}', t, t) = \langle \hat{\Psi}^\dagger(\mathbf{r}, t) \hat{\Psi}(\mathbf{r}', t) \rangle \quad (2)$$

$$\text{Fixed } \mathbf{r}: C(t, t') = C(\mathbf{r}, \mathbf{r}, t, t') = \langle \hat{\Psi}^\dagger(\mathbf{r}, t) \hat{\Psi}(\mathbf{r}, t') \rangle, \quad (3)$$

as these contain the primary information about spatial and temporal coherence.

The typical definition of equilibrium BEC is in the form of so-called off-diagonal-long-range order (ODLRO), associated with the nonvanishing asymptotic (spatial) behavior of the one-body density matrix $\rho(\mathbf{r}, \mathbf{r}', t) = \langle \hat{\Psi}^\dagger(\mathbf{r}, t) \hat{\Psi}(\mathbf{r}', t) \rangle$ (Pitaevskii and Stringari, 2016; Ueda, 2010; Leggett, 2006). In particular, ODLRO is defined by

$$\lim_{|\mathbf{r} - \mathbf{r}'| \rightarrow \infty} \langle \hat{\Psi}^\dagger(\mathbf{r}, t) \hat{\Psi}(\mathbf{r}', t) \rangle \neq 0, \quad (4)$$

with its value tending to some nonzero constant limit $\psi^*(\mathbf{r}, t) \psi(\mathbf{r}', t)$, consistent with the existence of off-diagonal correlations in the one-body density matrix. This introduces the quantity $\psi(\mathbf{r}, t)$ as the so-called order parameter of the system. To highlight the existence of a nonzero value, this is usually expressed as $\psi = |\psi|e^{i\theta}$, a form that facilitates an analogy to classical fluids through the mass density $\rho = m|\psi|^2$ and superfluid velocity $\mathbf{v} = (\hbar/m)\nabla\theta$ (Pitaevskii and Stringari, 2016).

Moreover, one often connects the BEC order parameter with the expectation value of the Bose field operator through $\psi(\mathbf{r}, t) = \langle \hat{\Psi} \rangle$. Such an argument is motivated by the analogous classical description of the electromagnetic field, in which one introduces a complex “classical” electric field as the expectation value of the corresponding (quantum-mechanical) electric field operator. While somewhat useful, there are some subtleties in following such procedure for massive particles, like atoms, which (unlike photons) cannot be created/destroyed from the vacuum by single-particle creation/annihilation operators: an insightful discussion of this issue, and the definition of BEC can be found in the book by Leggett (2006). While models explicitly maintaining the quantum-mechanical nature of the operator also exist, it is not essential to discuss such an extension here, with the reader instead referred to recent reviews (Proukakis and Jackson, 2008; Proukakis et al., 2013). For the purposes of this discussion, we approximate the actual field operator by a fluctuating classical field (obeying a classical probability distribution in phase space), thus accommodating both density and phase fluctuations into the subsequent description in a manner which significantly simplifies the direct numerical modeling (see later). All discussion, from this point onwards are thus expressed in terms of the complex/multimode classical field, which in this work will be denoted by $\Phi(\mathbf{r}, t)$ and also referred to occasionally as the order parameter.

When studying the correlation in a given system, it is often useful to deal with appropriately normalized correlation functions, denoted by $g^{(n)}$: for example, the above general expression (Eq. 1) (written now in terms of the classical field $\Phi(\mathbf{r}, t)$) can be

normalized by the product $\Pi_i \sqrt{\langle |\Phi(\mathbf{r}_i, t_i)|^2 \rangle \langle |\Phi(\mathbf{r}'_i, t'_i)|^2 \rangle}$. This is useful as it implies that the same-location (all $\mathbf{r}_i, \mathbf{r}'_i$ the same), equal-time (all t_i, t'_i the same) normalized correlation function $g^{(n)}(0)$ has the elegant limiting cases (Cohen-Tannoudji and Robilliard, 2001)

$$g^{(n)}(\mathbf{r}_i \cdots \mathbf{r}_i; t_i \cdots t_i) = \begin{cases} 1 & \text{(Purely Coherent)} \\ n! & \text{(Incoherent)} \end{cases}. \quad (5)$$

In what follows, I will use interchangeably the (unnormalized) correlation functions $C(\mathbf{r}, \mathbf{r}')$ and $C(t, t')$, or their normalized versions respectively defined by

$$g^{(1)}(\mathbf{r}, \mathbf{r}') = \frac{\langle \Phi^*(\mathbf{r}, t) \Phi(\mathbf{r}', t) \rangle}{\sqrt{\langle |\Phi(\mathbf{r}, t)|^2 \rangle} \sqrt{\langle |\Phi(\mathbf{r}', t)|^2 \rangle}}, \quad (6)$$

and

$$g^{(1)}(t, t') = \frac{\langle \Phi^*(\mathbf{r}, t) \Phi(\mathbf{r}, t') \rangle}{\sqrt{\langle |\Phi(\mathbf{r}, t)|^2 \rangle} \sqrt{\langle |\Phi(\mathbf{r}, t')|^2 \rangle}}. \quad (7)$$

Note that although Eqs. (6) and (7) are often considered independently, a combined analysis of these two quantities can provide further crucial information about the extent of the “equilibrium” (or “nonequilibrium”) nature of the system, or the emerging spatiotemporal scaling relations (see subsequent discussion on exciton-polaritons in Section “Driven-dissipative condensation in exciton-polariton systems”).

As previously mentioned, the hallmark of BEC in a 3D system is the striking emergence of ODLRO, signifying that (some degree of) coherence is maintained across all space, that is, $g^{(1)}(\mathbf{r}, \mathbf{r}'; t)$ tends to a nonzero-valued plateau (having a value between 0 and 1) as $|\mathbf{r} - \mathbf{r}'| \rightarrow \infty$: for a finite-size system, it is of course only meaningful to study the dependence of $g^{(1)}$ on $|\mathbf{r} - \mathbf{r}'|$ over the spatial extent of the (coherent part of the) system. In fact, the extent of deviation of the plateau value from the starting value of 1 (taken at $\mathbf{r} = \mathbf{r}'$) provides information about the fraction of incoherent particles coexisting with the condensed part (Cohen-Tannoudji and Robilliard, 2001).

Key emerging concepts utilized throughout this chapter, and described in more detail later, are those of self-similarity and scaling hypothesis. In a nutshell, the underlying idea is that under appropriate conditions (e.g., in a restricted spatial and/or temporal window) the microscopic details of the system are not relevant, with the physical description of key system observables acquiring a universal description in terms of appropriately rescaled variables and a specific functional form. Elimination of nonessential details at short scales (times) in favor of emphasizing large-scale (long-time) features—a key step in the universal description of a physical system associated with the analysis of critical phenomena and the concept of renormalization group theory (see, e.g., Nishimori and Ortiz, 2011; Binney et al., 1992; Bruce and Wallace, 1992)—is possible when there exists a characteristic lengthscale (timescale), which is much larger (longer) than all other relevant system scales (but smaller than the system size/evolution time). This in turn allows us to express relevant correlation functions over a limited spatial and/or temporal range in terms of a unique (but not *a priori* known) functional form whose arguments are appropriately rescaled spatial (temporal) variables, combined with a small number of critical exponents characterizing such behavior (Nishimori and Ortiz, 2011; Binney et al., 1992). Details of such scalings will become more apparent at relevant points throughout this chapter.

Given the existence of both density and phase fluctuations in a realistic system, it is natural to examine their interplay and relative importance. In general, as a system approaches quantum degeneracy from the incoherent regime, density fluctuations start becoming suppressed at an earlier point (larger value of $|\epsilon|$) than phase fluctuations. In the specific context of cooling (thermal phase transition), this implies the emergence of two distinct characteristic temperatures for suppression of density and phase fluctuations. This is particularly pronounced in lower effective dimensionalities (i.e., in quasi-1D and quasi-2D geometries) (Petrov et al., 2004), but such effect is still present in 3D geometries, even if largely obscured (and so, subdominant).

In order to also investigate the emergence of density fluctuations, we thus introduce here the second-order, or density–density correlation function (taken here for simplicity at equal times)

$$g^{(2)}(\mathbf{r}, \mathbf{r}', t) = \frac{\langle \Phi^*(\mathbf{r}, t) \Phi^*(\mathbf{r}', t) \Phi(\mathbf{r}, t) \Phi(\mathbf{r}', t) \rangle}{\langle |\Phi(\mathbf{r}, t)|^2 \rangle \langle |\Phi(\mathbf{r}', t)|^2 \rangle} = \frac{\langle n(\mathbf{r}, t) n(\mathbf{r}', t) \rangle}{\langle n(\mathbf{r}, t) \rangle \langle n(\mathbf{r}', t) \rangle}, \quad (8)$$

with local density–density correlations accessible by evaluating such quantity at $\mathbf{r}' = \mathbf{r}$.

As a direct consequence of Eq. (5), a pure BEC can be identified through $g^{(1)}(\mathbf{r}, \mathbf{r}, t) = g^{(2)}(\mathbf{r}, \mathbf{r}, t) = 1$, whereas an incoherent (thermal) field has $g^{(2)}(\mathbf{r}, \mathbf{r}, t) = 2$: this simple identification provides a further probe for testing the degree of coherence of a system at a given time t .

Penrose–Onsager condensation vs. quasi-condensation

The above discussion has introduced the concept of ODLRO for characterizing a condensate at equilibrium: However, one is typically dealing with a finite-size system, and so such discussion has to be necessarily limited to within the spatial extent of the

system (which should much exceed all other characteristic system lengthscales to make this nontrivial), and as limiting behavior in the thermodynamic limit.

In practice, for a finite-sized interacting system, one can instead proceed with a different characterization, following a seminal contribution by Penrose and Onsager (1956). In particular, one can diagonalize the off-diagonal one-body density matrix $\rho(\mathbf{r}, \mathbf{r}', t)$ to calculate its eigenvalues N_n through $\rho(\mathbf{r}, \mathbf{r}', t) = \sum_n N_n(t) \phi_n^*(\mathbf{r}, t) \phi_n(\mathbf{r}', t)$, where $\phi_n(\mathbf{r}, t)$ denotes the corresponding n -th eigenfunction. If in doing so one finds a macroscopically dominating eigenvalue, which is on the *same order* as the total particle number, then one can identify the mode corresponding to such eigenvalue with the Bose–Einstein condensate mode (Leggett, 2006). Mathematically, a dominant eigenvalue (if one exists) and corresponding eigenfunction of the density matrix can be identified from the solution of

$$\int d\mathbf{r}' \rho(\mathbf{r}, \mathbf{r}') \phi_n(\mathbf{r}') = N_n \phi_n(\mathbf{r}). \quad (9)$$

In practice one often uses a slightly relaxed criterion associated with the existence of a single eigenvalue which is much larger than all other eigenvalues of the system, but does not necessarily need to be on the same order as the total number of particles in the system. Such a mode is nowadays routinely referred to as the Penrose–Onsager mode of the system (and the above condition known as the Penrose–Onsager criterion) (Blakie et al., 2008).

In the context of numerical simulations of a fluctuating classical field, it is often numerically prohibitive to perform such a calculation by means of an ensemble/trajectory averaging. Thus, for purely practical reasons, one often resorts to time-averaging of a single trajectory as a numerical trick to achieve the same effect: the idea here is to compute the off-diagonal density matrix by averaging over a large number of samples spread over a timescale which is both longer than that governing the evolution of intrinsic fluctuations and shorter than any typical evolution of interest in the system (e.g., collective mode, large-scale motion of defects): in such a scenario, fluctuations in the field quickly randomize a single trajectory, thus making an average over different time evolutions of a single trajectory statistically analogous to averaging over many different independent trajectories: in other words, with careful choice of parameters, averaging over different time samples can also mimic the effect of averaging over different trajectories not only in a dynamical steady state in which the order parameter fluctuates about some mean value but also in a dynamical setting (Blakie et al., 2008). Note that global observables depending critically on the dynamical path additionally require averaging over (at least) a small number of trajectories to ensure the result is indeed statistically independent (and does not contain information about the system history): this is for example the case when probing correlation functions and defect numbers later in the context of quenched (Kibble–Zurek) dynamics in an inhomogeneous geometry (Section “Analyzing Kibble–Zurek in an elongated ultracold atomic system”).

At this stage it is important to also comment on the role of system dimensionality: As well known, ODLRO—and so BEC—is strictly speaking restricted to 3D (or higher) configurations, with corresponding homogeneous ideal 2D systems (for all $T \neq 0$) only exhibiting a reduced degree of coherence, known as quasi-long-range (or topological) order; such distinction arises despite the fact that both systems exhibit superfluidity (Pitaevskii and Stringari, 2016; Ueda, 2010). Reduced coherence in 2D arises as a result of the dominant role of long-wavelength excitations destroying the overall phase coherence of the system, according to the well-known Hohenberg–Mermin–Wagner theorem. In such a case, the system exhibits a distinct phase transition, known as the Berezinskii–Kosterlitz–Thouless (BKT) transition (Kosterlitz, 2017; Jos, 2013): this is associated for $\epsilon \gtrsim 0$ with the binding of the free vortices which typically proliferate above the critical temperature ($\epsilon > 0$)—and whose presence randomizes the system phase—into vortex–antivortex pairs; such binding effectively screens their existence, which can be visualized as annihilation. Thermal fluctuations in 2D at any nonzero temperature reduce the coherence of the system compared to the corresponding 3D case, with the corresponding spatial profile of the correlation exhibiting instead in 2D a power-law decay and quasi-long-range order (as opposed to ODLRO).

Given that the dominant factor in the behavior of the spatial correlation function $g^{(1)}(\mathbf{r}, \mathbf{r}')$ is the distance between the two points, that is, $|\mathbf{r} - \mathbf{r}'|$, and to simplify the expressions, here I arbitrarily choose to label one of these points as $\mathbf{0}$, and the distance between them as $\mathbf{r}$, such that the relevant normalized spatial correlation function takes the form $g^{(1)}(\mathbf{r}) = g^{(1)}(\mathbf{0}, \mathbf{r})$. Below the critical temperature ($\epsilon \rightarrow 0^+$)—and in the specific context of an infinite homogeneous system—this takes in the $r \rightarrow \infty$ limit the dimensionality-dependent form

$$g^{(1)}(\mathbf{0}, \mathbf{r})|_{0 < T < T_c} = \begin{cases} \text{constant} & (3\text{D}) \\ r^{-\alpha(T)} & (2\text{D}) \end{cases}, \quad (10)$$

with the value of the constant being temperature-dependent and lying between 0 and 1. In the above expression $\alpha(T) = 1/n_s \lambda^2$ is a temperature-dependent exponent characterizing the rate at which the correlation function decays to zero in a 2D system, which is inversely proportional to the superfluid density n_s . In an *equilibrium* 2D system, $\alpha(T) \lesssim 1/4$, with equality reached at the critical point $T = T_c$. Since no ODLRO can emerge in an infinite homogeneous 2D system (except for the specific case of $T = 0$), such a system cannot possess a condensate in the infinite limit. (Of course experimental systems are finite in nature, and so in confined atomic condensates one still often speaks of a “condensate” in the sense of significant coherence over the system size.) In that case one instead introduces a quasi-condensate, n_{qc} , which corresponds to that part of the density n which exhibits (relatively) suppressed density fluctuations, but whose phase is still largely fluctuating—this is possible due to the previously mentioned decoupling of the characteristic temperatures for the onset of phase and density fluctuations.

The quasi-condensate is defined as (Prokof'ev and Svistunov, 2002; Proukakis, 2006)

$$n_{qc}(\mathbf{r}) = n(\mathbf{r}) \sqrt{2 - g^{(2)}(\mathbf{r})}, \quad (11)$$

where $g^{(2)}(\mathbf{r}) = g^{(2)}(\mathbf{r}, \mathbf{r}; t, t)$. From a density matrix perspective, a quasi-condensate corresponds to a state with many relatively large eigenvalues of (broadly) comparable values. Put differently, a quasi-condensate arises when the system has multiple modes exhibiting relatively enhanced macroscopic occupation, but there is no single mode which can be identified as dominant. Although a quasi-condensate is thus a more natural state to consider in a lower dimensional setting (both in 2D and, for weakly interacting systems, also in 1D), it is important to note that such a state also plays a crucial (transient) role even in 3D systems during the formation stage of a true Bose–Einstein condensate: in a nutshell, the transition from an incoherent 3D system to a coherent 3D BEC precedes through states of quasi-condensation (Kagan et al., 1992; Proukakis et al., 2017; Berloff and Svistunov, 2002), which simply implies that, as the system occupation is redistributed toward lower momenta, there is initially some competition of various low-lying modes before one ultimately dominates and forms the Bose–Einstein condensate (in the sense of the dominant Penrose–Onsager mode).

The Penrose–Onsager mode exhibits both suppressed density and suppressed phase fluctuations. As such, this mode can also be (approximately numerically) reconstructed from the two lowest order correlation functions. For example, for the specific case of a harmonically trapped condensate which provides a natural peak in the condensate density at the trap center $\mathbf{r} = 0$, one can approximate (Al Khawaja et al., 2002; Cockburn et al., 2011) (for a fixed time t , suppressed here)

$$n_c(\mathbf{r}) = g^{(1)}(\mathbf{r}) \quad n_{qc}(\mathbf{r}) = g^{(1)}(\mathbf{r}) \sqrt{2 - g^{(2)}(\mathbf{r})} \quad n(\mathbf{r}). \quad (12)$$

Notwithstanding the above, I note that for finite systems trapped in inhomogeneous potentials, such as harmonic traps, the system maintains sizeable coherence over its spatial extent, as the trap sets a lower limit for the momenta of the elementary excitations, thus suppressing the extent of phase fluctuations. As a result, in the limit of relatively low temperatures (much below T_c), one can still identify the equilibrium state of the system as a “true” BEC (Petrov et al., 2004; Al Khawaja et al., 2002; Ueda, 2010).

Workhorse model of Bose–Einstein condensation

The usual (and simplest) textbook description of a continuous phase transition is in terms of a phenomenological Ginzburg–Landau model, whose free energy functional takes the general form (Leggett, 2006)

$$F[\Phi(\mathbf{r})] = \int d^3\mathbf{r} \left[F_0 + \alpha |\Phi|^2 + \frac{\beta}{2} |\Phi|^4 + \gamma |\nabla \Phi|^2 \right], \quad (13)$$

for an appropriate (system-specific) choice of parameters α , β and γ . The usefulness of such a model is that it supports a phase transition from a symmetric state with a global minimum of the free energy when $\Phi = 0$, to a Mexican-hat style potential exhibiting a minimum at a $\Phi \neq 0$ value (see illustration in subsequent Fig. 6): in other words, it facilitates—under appropriate conditions—the emergence of a nonzero order parameter of the system.

In the context of BEC, such a model is cast in terms of a nonlinear Schrödinger equation—known as the Gross–Pitaevskii (GP) equation—which takes the form (Pethick and Smith, 2002; Pitaevskii and Stringari, 2016; Ueda, 2010; Dalfovo et al., 1999)

$$i\hbar \frac{\partial \Phi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \Phi + V\Phi + g|\Phi|^2 \Phi. \quad (14)$$

Here m is the mass of the (composite) boson, V is the external potential, and g is the effective interaction strength between constituent bosons, assumed here for simplicity to be local [i.e., $V(\mathbf{r} - \mathbf{r}') = g\delta(\mathbf{r} - \mathbf{r}')$], based on the lowest order (or s-wave) scattering process. This equation is often explicitly written with an additional $-\mu\Phi$ term on the right-hand-side, where μ is the system chemical potential.

This equation arises both as (trivially) the lowest order equation for the symmetry-broken field $\Phi = \langle \hat{\Psi} \rangle$, and as the effective (low-energy) field equation for a semi-classical field (or order parameter) Φ —the latter applicable for all highly-occupied modes in the system (i.e., those with occupation exceeding one particle per mode): for more information, see recent reviews (Proukakis and Jackson, 2008; Proukakis et al., 2013; Berloff et al., 2014; Blakie et al., 2008).

Beyond ultracold atomic gases, an appropriately modified form of this equation, which takes account of specific system details (e.g., nonlocal interactions, pumping, dissipation, rotation, gravitational effects), is applicable (with some limitations) to a range of diverse systems including liquid helium (Berloff, 1999), photon (Klaers et al., 2010) and exciton-polariton condensates (Carusotto and Ciuti, 2013), neutron star superfluidity (Warszawski et al., 2012; Drummond and Melatos, 2017; Verma et al., 2022), and fuzzy dark matter (FDM) (Marsh, 2016; Hui, 2021; Ferreira, 2021)—many of which are more explicitly discussed in subsequent sections. Specifically to account for a coupling to a heat bath (e.g., providing pumping, and/or dissipation), and the associated dynamical stochasticity, one often further supplements the above picture with further pumping/dissipation terms and an associated (typically additive) noise contribution, thus generalizing the “basic” Ginzburg–Landau model of Eq. (13) to a stochastic complex Ginzburg–Landau equation (see also subsequent Eqs. (15) and (32)).

Having identified the relevant physical systems, key considerations, and quantities useful in their description, I proceed to discuss features of universal dynamics emerging during the phase transition crossing (Section “Universality during phase transition crossing: The Kibble–Zurek scaling law”) and the subsequent system phase-ordering and relaxation to the final (equilibrium) state (Section “Universality during phase-ordering dynamics”)—with some emphasis on ultracold atomic gases as the physical system. Further remarks in the context of driven-dissipative quantum gases and other related features are then discussed in Section “Selected further considerations,” with some overall concluding remarks in Section “Conclusion.”

Key to the subsequent discussion is the idea of a scaling hypothesis in the spatial—and, by extension, also the temporal—domain, that is, the idea that correlation functions acquire in some limited “universal” regime the same functional form, in terms of a limited set of parameters—with the obvious example being that of a time-dependent lengthscale—and a specific set of exponents describing such dependence. Interestingly, the concepts discussed below are interdisciplinary, benefiting from cross-fertilization of ideas between (among other fields) condensed-matter theory, statistical physics, elementary particle theory, and cosmology.

Universality during phase transition crossing: The Kibble–Zurek scaling law

Early ideas

The concepts of spontaneous symmetry breaking and order formation at a critical temperature in ferromagnets and superconductors have found analogs in the context of the hot big bang model, with the universe transiting from a symmetric, to a symmetry-broken phase. Building on such (mathematical/notional) analogies, Tom Kibble wrote a seminal paper discussing the formation, topology, and evolution of domains emerging during a dynamical (second-order) continuous phase transition in the context of early-universe cosmology (Kibble, 1976). In such work, Kibble noted the initial chaotic formation of small quasi-ordered localized regions, or “protodomains,” between which the system expectation value would vary randomly from region to region as the system breaks its $U(1)$ symmetry, and starts choosing a preferred phase. In particular, Kibble raised the question of whether any residue of such protodomains may remain detectable—in the form of a long-lived topologically stable structure such as monopole, string, or domain wall—as the overall system coherence grows: such a structure would form naturally at the interface of two spatially separated regions of different phase. This question has since been appropriately reformulated, finding significant applications in diverse lab-based condensed-matter systems (including liquid helium, liquid crystals, superconductors, and trapped ions), owing to the intuition of Wojciech Zurek who later discussed the analogy between such cosmological strings and vortex lines in a superfluid in 1985 (Zurek, 1985), and thus proposed schemes for its experimental study.

For completeness, I briefly note here that analogies between superfluids and the early universe are abundant, with liquid helium having been proposed as a system in which to study a range of different phenomena of relevance to the physics of the universe (Zurek, 1996; Volovik, 2009; Pickett, 2017), considerations which have since been extended to other controlled quantum gases (ultracold atomic systems and exciton-polariton condensates) in which aspects such as analog gravity (Jacquet et al., 2020), false vacuum decay (Fialko et al., 2015; Billam et al., 2022), and hydrodynamic QCD plasma analogs (Adams et al., 2012) are currently under investigation.

A schematic from the pioneering work of Zurek is shown in Fig. 5A, depicting a quench in a very thin (so effectively one-dimensional) doughnut-shaped (annular) helium superfluid of radius R (Fig. 5A) (Zurek, 1985, 1996): Building on the idea of “protodomains,” let us consider that—at the time the system crosses the phase transition dynamically—the typical correlation length of the system takes a characteristic value ξ ; in other words, the system density around the ring circumference is divided into a number of regions, of effective mean length ξ , each of which exhibits a constant phase, but such phase is chosen independently, and thus randomly, across different locations around the ring with no causal connection between them. Assuming a random walk of the phase between regions, a net (nonzero) phase gradient can emerge from the phase mismatch $\Delta\theta$ around the ring, which is in turn translated into a superfluid velocity via $v_s = \hbar/m\nabla(\Delta\theta)$. Zurek thus concluded that a rapid phase transition quench (pressure quench in the case of liquid helium) could leave the superfluid rotating around the annulus, that is, a (random) nonzero circulation. By the structure of the order parameter $\Phi = |\Phi|e^{i\theta}$, such circulation would then be in the form of integer multiples of 2π , corresponding to persistent currents around the ring—with the value of the integer multiple characterizing the so-called winding number. The emergence of such persistent currents was predicted to occur stochastically with the most likely outcome being the absence of a persistent current.

Stochastic formation of persistent currents through a quenched phase transition of a condensed matter system in the specific context of such a (single) annulus has been experimentally studied in a single superconducting ring (Monaco et al., 2009) (see also related earlier references therein), and, more recently, in an ultracold atomic gas ring (Corman et al., 2014)—the latter briefly discussed in the next section. However, it is important to note at this stage—as will become clearer later—that the proposed Kibble–Zurek mechanism is very general and, as such, has been observed in a range of controlled quench experiments across different systems, such as liquid helium (Hendry et al., 1994; Bäuerle et al., 1996), superconductors (Carmi et al., 2000), liquid crystals (Chuang et al., 1991), multiferroics (Chae et al., 2012), trapped ions (Ulm et al., 2013), and single-component trapped ultracold atoms (Weiler et al., 2008; Lamporesi et al., 2013; Corman et al., 2014; Chomaz et al., 2015; Navon et al., 2015; Donadello et al., 2016; Aidelsburger et al., 2017; Ko et al., 2019)—see recent reviews (del Campo and Zurek, 2014; del Campo et al., 2013; Beugnon and Navon, 2017) for more details.

Numerical phase transition model

Although interesting nonequilibrium properties of the system can be studied by the Gross–Pitaevskii equation (Eq. 14) for classical field subject to appropriate initial choice of nonequilibrium states (see discussion in subsequent Section “Evolution around nonthermal fixed points”), a commonly used alternative, which further introduces the element of (dynamical) stochasticity to the system, is a slightly generalized version in the form of the so-called Stochastic Gross–Pitaevskii equation (Stoof and Bijlsma, 2001; Gardiner and Davis, 2003; Proukakis and Jackson, 2008; Blakie et al., 2008; Proukakis et al., 2013; Berloff et al., 2014)

$$i\hbar \frac{\partial \Phi}{\partial t} = \mathcal{P} \left\{ (1 - i\gamma) \left[-\frac{\hbar^2}{2m} \nabla^2 \Phi + V\Phi + g|\Phi|^2\Phi - \mu\Phi \right] + \eta \right\}. \quad (15)$$

This is a nonlinear Langevin equation corresponding to an effective field theory for the low-energy modes of a system: implicit in this model is that such modes are driven by their coupling to higher lying modes (representing a bath of purely thermal particles having an effective chemical potential μ and temperature T) through the dissipation strength γ , which—together with T —sets the mean strength of the fluctuations; the latter are treated as Gaussian noise with δ -correlations in both space and time, that is, $\langle \eta^*(\mathbf{r}, t) \eta(\mathbf{r}', t') \rangle = \bar{\eta}^2 \delta(\mathbf{r} - \mathbf{r}') \delta(t - t')$, where $\bar{\eta} = \sqrt{2\hbar\gamma k_B T}$. A projector $\mathcal{P}$ has also been included in Eq. (15) to ensure numerical consistency, by restricting dynamics within the same low-energy band of modes (Bradley et al., 2008; Blakie et al., 2008; Berloff et al., 2014).

Based on such simple techniques, one can numerically visualize phase evolution within Zurek’s original annular ring-trap setting in the context of ultracold quantum gases: this was beautifully demonstrated for the (effectively 1D) case of a very narrow annulus in Das et al. (2012). Corresponding results, generalized to a 2D setting such that the annulus width, w is also explicitly taken into consideration, thus facilitating also radial phase gradient and dynamics are shown in Fig. 4B. During such evolution, the dynamical noise η can drive an initial random phase into distinct regimes, having either zero net circulation (the most likely outcome, top right plot in Fig. 4B) or a nonzero phase winding of an integer multiple of $\pm 2\pi$ around the loop: in this particular example, the nonzero winding number generated is $n_w = 1$ (bottom right plot in Fig. 4B).

Such features were explicitly verified experimentally in ultracold atomic gases in Corman et al. (2014), finding a spread of winding numbers around a zero mean value. The detection was done by removing the ring potential and allowing the annular condensate to expand and interfere with an independent (reference) condensate formed in the center of the ring: a nonzero

Fig. 4 Phase evolution in an annular geometry (ring trap). (A) Original thought experiment of Zurek about an ultra-thin, effectively 1D ring in which the crossing of the phase transition induces typical domains of mean size $\xi \ll R$, where R is the ring radius. (B) Typical phase profile evolution in a 2D ultracold atomic gas based on SPGPE simulations of Eq. (15): a truly random, incoherent, initial state whose phase varies wildly within the ring (left) can follow under external parameter quenching different random paths of establishing larger regions of constant, but random, phase (middle), with this ultimately leading—for example—to the establishment of essentially constant phase across the ring (right, top), or a variation of 2π (right, bottom), that is, respectively a winding number n_w , or “charge” of 0, or 1. (C) (i) Dependence of mean winding number modulus $\langle |n_w| \rangle$ on mean ring radius R and ring width w through their ratio (R/w) (blue points) and corresponding prediction based on Zurek’s random region formation scenario (dashed line). (ii) Probability of occurrence of different winding number outcomes, n_w , in the quenched experiment of Corman et al. (2014) (red bars) and corresponding SPGPE predictions (blue bars) (Bland et al., 2020): the asymmetry in the experimental measurements is likely due to a smaller number of trajectory averaging over numerical simulations. circulation could then be inferred from spiral distributions in the density, detected destructively through absorption imaging. A numerical confirmation (based on Eq. (15)) of the anticipated mean winding number scaling in terms of the ring radius R and width w , namely $\langle |n_w| \rangle = \sqrt{2\pi R/w}$, and a comparison demonstrating excellent agreement of numerically generated and observed winding numbers in the experimental set-up are respectively shown in Fig. 4C(i)–(ii) (Bland et al., 2020).

Zurek’s original analysis and extensive follow-on work have led to the establishment of what is now known as the universal Kibble–Zurek scaling law of defect formation in a quenched quantum liquid. In order to be in a position to discuss such dynamical crossing of a phase transition more explicitly, I should first comment on equilibrium features around a critical point, ideas which will subsequently be appropriately extended to provide a universal description of nonequilibrium phase transition dynamics.

Criticality at equilibrium

As the system is probed on the incoherent side through different equilibrium states of decreasing temperature, the coherence length of a system, characterizing the spatial variation of the first-order correlation function, increases. Standard statistical physics considerations and critical phenomena theory enable us to describe the system correlations in terms of universal scaling relations, independent from the microscopic details of the system, and specified in terms of the distance to criticality, in a manner specified by a set of critical exponents and a scaling function (Binney et al., 1992; Nishimori and Ortiz, 2011): such considerations are a key aspect of the present discussion.

A striking example of the universal approach to criticality is the divergence of the system coherence length L at the actual system critical point: on the incoherent side of the phase transition, such approach is characterized via $g^{(1)}(\mathbf{r}) \sim e^{-r/L}$; this is in fact a very useful observable in order to identify the precise location of a critical point (either experimentally or numerically within a given model); such points will in general be slightly shifted due to quantum fluctuations, interaction, and finite-size effects (Dalfovo et al., 1999; Holzmann et al., 2004). One generally quantifies this by defining a “distance to criticality” parameter ϵ , which is measured as the difference of the value of ϵ in a given configuration from the critical value ϵ_c which signifies the transition point (the latter typically taken as $\epsilon_c = 0$).

Although the existence of a divergence at criticality is broadly applicable, the way that such a divergence manifests itself depends sensitively on the system dimensionality and symmetry and interaction properties of the underlying system Hamiltonian (which, in turn, define the corresponding order parameter for the particular phase transition being considered) (Binney et al., 1992). Systems whose approach to criticality (for a continuous phase transition) obey the same scaling functions and the same diverging behaviors in terms of $|\epsilon|$ are said to belong to the same universality class (Nishimori and Ortiz, 2011): the Bose gas (ultracold bosonic atoms, λ transition in ^4He) belongs to the XY universality class, and thus its critical properties are expected to exhibit the same behavior as the XY model. However, as should be anticipated from the preceding discussion, 3D and 2D systems do not exhibit the same behavior near criticality (they have distinct critical behavior/exponents), and this is also related to the very different nature of the phase transition: BEC vs. BKT.

Once the approach to criticality has been identified, one can specify the relevant information for the transition in terms of the values of the relevant critical exponents characterizing such divergence as a function of $|\epsilon|$: systems having the same dimensionality and the same critical exponents are said to belong to the same universality class. To make this more specific, let us consider the correlation length ξ in an infinite 3D system undergoing BEC through cooling, for which the distance to criticality, ϵ , is defined according to $\epsilon = (T_c - T)/T$. In the $\epsilon \lesssim 0$ limit (corresponding to $T > T_c$) this is expected to diverge in the vicinity of the critical point, that is, at $\epsilon \rightarrow 0^-$, as

$$\xi = \xi_0 |\epsilon|^{-\nu} = \xi_0 \left| \frac{T - T_c}{T_c} \right|^{-\nu}, \quad (16)$$

where ξ_0 is a nonuniversal parameter depending on the specific system microphysics (which is thus not considered further here) and ν is the static critical exponent. In the case of ultracold atoms, ν has been measured as $\nu \approx 0.67$ (Donner et al., 2007) (consistent with expectations of the 3D XY model). An example of such behavior is shown in Fig. 5A. Note that in a 2D system, the behavior of the coherence length near criticality takes a more stringent form $\xi \sim \exp(b|\epsilon|^{-\nu})$ (where $b \sim O(1)$ is a constant) (Jelić and Cugliandolo, 2011), with the exact form still under discussion.

Criticality in a dynamical setting

Generalizing to a dynamical setting, it should be noted that the relaxation dynamics of a system, that is, the process by which the system equilibrates in a given configuration (i.e., for a fixed value of ϵ) from a nonequilibrium initial condition, is dramatically slowed down near the transition point; this is intricately related to the fact that the correlation length of the system, that is, the distance over which the system has to achieve phase coherence, is—as previously discussed—rapidly increasing in the vicinity of the critical point. The associated increase (divergence) in time required for the relaxation process is known as critical slowing down (Nishimori and Ortiz, 2011). In fact, the relaxation time (in the 3D BEC system under discussion), also known as correlation time, diverges according to [see Fig. 5B]

Fig. 5 Divergence of (A) equilibrium correlation length and (B) correlation time in the vicinity of a phase transition occurring at $T = T_c$ (or $\epsilon = 0$): (A) Main plot shows the diverging correlation length ξ (red line) as the system approaches criticality from higher temperatures (i.e., from the right); characteristic snapshots of the unnormalized first-order spatial correlation function $G^{(1)}(r)$, which decays as $1/r$ with the distance from the trap center, are shown at three different temperatures, that is, at different values of ϵ (filled blue curves). Inset: Temperature dependence of the overall system condensate fraction (green curve), with the gray band in the immediate vicinity of, and specifically above, the critical point depicting the temperature region probed in the main plot. (B) Divergence of correlation time assumed symmetric on both sides of the transition, and plotted here in terms of $\epsilon = (T_c - T)/T$ for ease of comparison with subsequent time-dependent discussion. Expressions quoted in each case summarize our understanding of equilibrium criticality as a function of temperature T , demonstrating the relation $\tau \sim \xi^z$. (A) Reprinted with permission from Donner T, Ritter S, Bourdel T, Ottl A, Köhl M, and Esslinger T (2007) Critical behavior of a trapped interacting Bose gas. $$\tau = \tau_0 |\epsilon|^{-\nu z} \sim \xi^z. \quad (17)$$

This additionally introduces the dynamical critical exponent z governing intrinsic system evolution at a fixed value of $|\epsilon|$: note that τ_0 appearing here is a nonuniversal time containing details of microscopic properties.

Having discussed the path to equilibration for a given value of ϵ , one can now proceed to consider the dynamical quench scenario, and thus address the question of the system dynamics when the distance to criticality is itself tuned in a dynamical manner, that is, $\epsilon \rightarrow \epsilon(t)$. The simplest, and standard, scenario considered is that of a linear variation of the distance to criticality with evolution time, which is assumed to occur over a characteristic quench timescale τ_Q , that is,

$$\epsilon(t) = \frac{t}{\tau_Q}. \quad (18)$$

As such, τ_Q controls the effective quench rate: small τ_Q implies the system is moving rapidly through different regimes along the ϵ axis, that is, small τ_Q corresponds to rapid quenches; conversely, the adiabatic crossing of the phase transition (through equilibrium states) is achieved in the limit $\tau_Q \rightarrow \infty$.

The evolution of the system from an (incoherent) state without symmetry-breaking (left) to a broken-symmetry one [which supports the formation of a phase-coherent state] (right) is shown schematically in Fig. 6 in terms of the time-dependent distance to criticality, with $\epsilon(t) = 0$ indicating the equilibrium critical point (del Campo and Zurek, 2014). Shown in this figure are two curves: the diverging correlation time (dashed black lines) and an instantaneous system-adjustment timescale constructed from the rate of quenching across the phase transition (i.e., the rate of change of the distance to criticality $\dot{\epsilon}$) through the relation $t = \epsilon/\dot{\epsilon}$. By convention, during the dynamical crossing of the phase transition, the time of the transition corresponds to $t = 0$, with $t < 0$ (corresponding to $\epsilon < 0$) labeling the incoherent side of the transition, and $t > 0$ the coherent side. Our understanding of the dynamics of the phase transition can be cast in terms of the relative magnitude of these two times (correlation time and system-adjustment timescale).

As the system moves toward the critical point (starting from an incoherent equilibrium state), the time taken for the system to adjust to its new instantaneous equilibrium solution grows, and starts doing so very rapidly as it approaches closer to the (equilibrium) critical point (where it diverges). Thus, necessarily, as the system is dynamically induced through the phase transition, the situation will arise, in which the rate at which the system is driven through the phase transition parameter space is so fast that its corresponding inverse timescale is shorter than the time required for the system to equilibrate over an increasing lengthscale; this happens when the correlation time τ becomes (in the vicinity of the critical point) larger than the magnitude of the instantaneous timescale $|\epsilon/\dot{\epsilon}|$, associated with the rate of quenching. Beyond such time, the system no longer has enough time to adjust as a whole

Fig. 6 Schematic of the “cartoon” Kibble–Zurek scenario, describing the phase transition from an incoherent to a coherent state through a dynamically induced linear crossing of the distance to criticality $\epsilon(t)$ in time. Shown in terms of $\epsilon(t)$ are the correlation time, which diverges from both sides as $\epsilon(t) \rightarrow 0$ [dashed red line] and an instantaneous timescale $\epsilon/\dot{\epsilon}$ set by the rate at which the quench is induced. Regarding the latter, I note here that when plotting things in terms of $\epsilon(t)$, slower quenches have a steeper slope of $|\epsilon/\dot{\epsilon}|$, thus allowing the system to reach, in principle, arbitrarily close to the critical point before it can no longer adiabatically follow equilibrium states in its crossing through the phase transition. During its crossing, the system can only adiabatically follow corresponding equilibrium states for as long as $|\tau| < |\epsilon/\dot{\epsilon}|$; otherwise, the characteristic correlation length setting the size of the domains becomes frozen to its value, $\xi = \xi(\epsilon)$ evaluated at $\epsilon = \epsilon(-\hat{t})$ and the system behaves impulsively between $-\hat{t}$ and $\hat{t}$. The symmetry of the prequench (symmetric, $\langle \Phi \rangle = 0$) and postquench (symmetry-broken, $\langle \Phi \rangle \neq 0$) equilibria of the system are depicted in terms of the thermodynamic potential with the radial direction depicting the absence (left) or existence (right) of a nonzero order parameter: in the latter case, and while the azimuthal angle in this “Mexican hat” potential can in principle take any value with equal probability, the merging dynamics of domains of spontaneously generated random phases ultimately leave the system at sufficiently large values of $\epsilon > 0$ (and in this case at sufficiently late, or asymptotically long, times such that all critical transient dynamics have died out) with a particular spontaneously chosen direction, or phase θ (whose gradient sets the superfluid velocity).

to the external quench, and so different parts of the system necessarily evolve independently of each other, no longer controlled by the external drive (e.g., cooling ramp); in other words, the system is allowed to evolve independently on a local scale, and so the global symmetry is broken. This implies that the thermodynamic potential of the system transitions suddenly from a single minimum at the origin corresponding to the absence of any identified order parameter, that is, $\langle \Phi \rangle = 0$, to a typical “Mexican-hat” potential with $\langle \Phi \rangle \neq 0$ (see Fig. 6); in such a potential, the radial location of the minima indicates a nonzero expectation value of the system order parameter Φ , which thus acquires a meaning on this side of the phase transition while the azimuthal direction contains information about the phase of Φ . Note that, at this stage, all minima in such a potential, corresponding to different azimuthal orientation (at fixed radial distance), become equally probable, that is, all local phase choices are equally likely; this in turn implies that the phase varies randomly (following a random walk) between different domains, the size of which is (typically much) smaller than the system size. In fact, the typical size of such domains is set by the equilibrium correlation length of the system evaluated at the distance to criticality ϵ corresponding to the time when the symmetry is broken.

The Kibble–Zurek scaling law

Having introduced the key concepts, one can now formulate the fundamental equations governing the Kibble–Zurek mechanism of quenched phase transitions. The underlying idea is to use the equilibrium behavior of the system near criticality to make specific predictions regarding the nonequilibrium consequences of the dynamics of symmetry breaking. Mathematically, this relies on identifying the characteristic time at which the instantaneous quench timescale $|\epsilon/\dot{\epsilon}|$ [diagonal lines in Fig. 6] becomes equal to the diverging relaxation timescale τ : such time, typically denoted by $\mp\hat{t}$, signifies the so-called freeze-out time, that is, the time during the quench when the system behavior ceases being identified by parameters adiabatically following the equilibrium properties of the system as a whole (at a rate set by the quench rate). The typical size of subsequent independent domains—which have (in this simplistic scenario) no causal connection between them—is then set by the instantaneous value of the system correlation length at the freeze-out time. The discussion below follows closely the review articles (del Campo et al., 2013; del Campo and Zurek, 2014) based on the considerations by Kibble and Zurek.

Mathematically, one equates the diverging relaxation time τ , evaluated at the freeze-out time $-\hat{t}$, to the time $|\hat{t}|$ set by $|\epsilon(-\hat{t})/\dot{\epsilon}(-\hat{t})|$. The fundamental Kibble–Zurek relation can thus be written as

$$\tau(-\hat{t}) = |\hat{t}|, \quad (19)$$

As the above equation simply labels the two points of intersection of the solid and dashed lines in Fig. 6, which are the same in this (presumed symmetric) schematic across both sides of the phase transition, one often quotes this as the more “memorable” and algebraically equivalent form $\tau(\hat{t}) = \hat{t}$. Since the quench rate $\epsilon(t)$ depends on the quench timescale, τ_Q , then so do the above-mentioned intersection points, thus characterizing the dependence of correlation time—and, by extension, of correlation length (during the quenched evolution)—on τ_Q .

In its most basic (and most commonly presented) form (discussed here), the Kibble–Zurek scenario considers the system dynamics as being “frozen” between $-\hat{t}$ and $+\hat{t}$ (i.e., when $\tau > |\hat{t}|$), with such temporal window—during which the system remains fragmented into a number of smaller domains, exhibiting no correlation between them—labeled as the “impulsive” regime.

To understand the implications of such relation further, let us now consider a specific case—namely the example of a 3D homogeneous system, known to obey the equilibrium critical scalings of Eqs. (16) and (17). In that case, one can re-express Eq. (19) [or its equivalent relation $\tau(\hat{t}) = \hat{t}$] as

$$\tau(\hat{t}) = \tau_0 |\epsilon(\hat{t})|^{-\nu z} = \tau_0 \left| \left(\frac{\hat{t}}{\tau_Q} \right) \right|^{-\nu z} = \hat{t}. \quad (20)$$

Such a relation allows us to obtain a characteristic scaling of the freeze-out time, $\hat{t}$, in terms of τ_Q , with a corresponding relation for $\hat{\xi}$ obtained through $\hat{t} = \hat{\xi}^z$. Ignoring microscopic prefactors, which are not relevant for the universal system dynamics, one thus deduces that (for a homogeneous 3D system)

$$\hat{t} \sim \tau_Q^{\nu z / (1 + \nu z)}, \quad (21)$$

and correspondingly

$$\hat{\xi} = \xi(\epsilon(\hat{t})) = \xi_0 |\epsilon(\hat{t})|^{-\nu} \sim \tau_Q^{\nu / (1 + \nu z)}. \quad (22)$$

Although the Kibble–Zurek relation (Eq. 19) will always specify a characteristic scaling for $\hat{t}$ and $\hat{\xi}$ in terms of τ_Q around criticality, the exact form (and arising exponents) of such emerging relations will depend on the dimensionality and universality class of the system—with these results requiring revisiting in an inhomogeneous context (see later).

We have thus identified the timescale $\hat{t}$ and length scale $\hat{\xi}$, as the dominant relevant scales in the system in the critical region. As such, within such limited regime, one can formulate the temporal and spatial dependence of physical variables in the system in a universal manner by a simple rescaling of the form

$$\begin{aligned} \text{Time} & \quad t \rightarrow t/\hat{t} \\ \text{Distance} & \quad \mathbf{r} \rightarrow \mathbf{r}/\hat{\xi} \\ \text{Wavevector} & \quad \mathbf{k} \rightarrow \mathbf{k}\hat{\xi} \end{aligned}$$

Having identified the relevant scales in the system allows us to formulate the corresponding scaling hypothesis for the system correlations (applicable in the long-wavelength, low-frequency limit); in the discussion below I also ignore for simplicity the anomalous critical exponent (denoted by η), as its value is typically zero or very close to it (Nishimori and Ortiz, 2011; Binney et al., 1992). The Kibble–Zurek scaling hypothesis thus states that in the critical region $[-\hat{t}, \hat{t}]$, the correlation function can be cast in the form

$$C(\mathbf{r}, t) \sim \frac{1}{\hat{\xi}^{d-2}} F\left(\frac{t}{\hat{t}}, \frac{\mathbf{r}}{\hat{\xi}}\right), \quad (23)$$

where F is some system-specific function, and d is the system dimensionality. In general, this implies that the correlation function is dynamically evolving in a manner that changes both its shape and its range. However, the discussion so far has been focused on the (adiabatic-impulsive-adiabatic) “cartoon” Kibble–Zurek scenario of Fig. 6; it is thus pertinent to note here that while such a “cartoon” picture is indeed consistent with the scaling function of Eq. (23), it nonetheless further constrains it by implying a particular (time-independent) form for F .

Setting this aside for now, I note that the Kibble–Zurek relation of Eq. (19) enables us to predict the scaling of the number of defects spontaneously generated within such system during the linearly quenched phase transition crossing with the quench timescale τ_Q . Based on the typical size of independent domains $\hat{\xi}$ in the broken-symmetry phase (set by the equilibrium correlation length ξ evaluated at the freeze-out time $-\hat{t}$), and information about the system dimensionality, d , and defect dimensionality, $\mathcal{D}$, this takes the form (del Campo et al., 2013)

$$n_{\text{defect}} \sim \left(\frac{\hat{\xi}^{\mathcal{D}}}{\hat{\xi}^d} \right) \sim (\tau_Q)^{-\alpha}, \quad (24)$$

where the exponent $\alpha > 0$ in general depends on the critical exponents (ν, z) and the system/defect dimensionalities ($d, \mathcal{D}$). For example, $(d - \mathcal{D}) = 1$ for a 2D planar soliton in a 3D system or a point-like solitonic defect in a 1D system, while $(d - \mathcal{D}) = 2$ in both cases of a linear vortex filament in a 3D system, or a point-like vortex defect in a 2D system, because two dimensions are needed to accommodate the phase profile around such a vortex. As expected, one finds that—compared to slow quenches—faster quenches (i.e., small τ_Q) for which $|\epsilon/\dot{\epsilon}|$ has a smaller slope, and thus yields a smaller value of $\hat{\xi}$, lead to the generation of more defects; this is because more independent regions of smaller size can be accommodated in a given system size. In the specific 3D homogeneous example, $\alpha = (d - \mathcal{D})\nu / (1 + \nu z)$, whereas this becomes modified in the presence of harmonic confinement (see later). The power of the presented “cartoon” Kibble–Zurek mechanism is that it predicts the correct *scalings* with τ_Q for a linearly quenched homogeneous system. Nonetheless, an immediate shortcoming of such adiabatic-impulsive-adiabatic scenario, which can be identified, is that it ignores the temporal growth of correlations within the critical region; moreover, realistic experiments (besides being performed in finite-size systems) are often conducted in spatially varying potentials, thus requiring the extension of such mechanism to inhomogeneous settings. Both these issues are addressed in Sections “Analyzing Kibble–Zurek in an elongated ultracold atomic system” and “Beyond homogeneous Kibble–Zurek considerations.”

In the context of ultracold atom experiments, beyond the previously-mentioned ring-trap geometry (Corman et al., 2014; Aidelburger et al., 2017), the Kibble–Zurek phenomenon across a thermal phase transition has also been studied in different

settings, including box-like geometries in 3D (Navon et al., 2015) and 2D (Chomaz et al., 2015), elongated 3D (Lamporesi et al., 2013; Donadello et al., 2016; Liu et al., 2018; Wolswijk et al., 2022) and oblate (pancake-like) (Goo et al., 2021, 2022; Kim et al., 2022) inhomogeneous traps, and even in the context of strongly interacting fermionic superfluids (Ko et al., 2019) (Tuning the interactions across the BEC-BCS crossover through the unitarity limit in a strongly-interacting superfluid revealed a near-constant, that is, interaction-strength-independent, critical exponent α).

The insightful experiment at Cambridge in a 3D box-like geometry (Navon et al., 2015) probed the system spatial correlation function at different times, by interfering the system with a displaced copy of itself: they used such measurements to explicitly demonstrate the existence of critical slowing down; by determining the scaling of the correlation length with τ_Q —and using the expected (and previously experimentally extracted (Donner et al., 2007) value of $\nu \approx 2/3$ discussed earlier)—they were able to show that the dynamical critical exponent $z = 3/2$, consistent with the expectation for the 3D XY model universality class. Many of these early ultracold experiments also probed the number of generated vortices during a controlled quench, and its dependence on the quench timescale τ_Q (Corman et al., 2014; Chomaz et al., 2015; Donadello et al., 2016) (see subsequent discussions for more recent works). On the whole, good overall agreement with the expected behavior was obtained for sufficiently slow quenches as long as other appropriate factors, such as dimensionality and type of confinement (e.g., harmonic, ring-trap), were taken into account; however, a common potential limitation in such cases arises from the fact that experimental defect counting is typically only possible at times significantly longer than $+ \hat{t}$ (which can generally be rather restrictive for most defect types due to their relatively short lifetimes), or after allowing the system to relax and/or expand for some time to make defect detection easier; such aspects are further discussed below.

Analyzing Kibble–Zurek in an elongated ultracold atomic system

To gain further direct microscopic insight into the complex system dynamics over all timescales and physical observables, and probe the physics beyond the “cartoon” Kibble–Zurek picture presented so far, I briefly review here key results obtained in the context of a particular sequence of experiments conducted at Trento in an elongated 3D harmonic geometry (Lamporesi et al., 2013; Donadello et al., 2016; Liu et al., 2018; Wolswijk et al., 2022). In such experiments, the system was cooled through the phase transition at different rates $\dot{T}$, with approximately fixed initial and final states.

A schematic of such process—based on extensive numerical simulations (Liu et al., 2018) via Eq. (15)—is shown in Fig. 7. An initially incoherent gas is dynamically quenched through the critical point (which is itself shifted by the combination of fluctuations and mean-field effects). As predicted, the system reacts (“unfreezes” its dynamics) with a certain delay time $+ \hat{t}$ after crossing the equilibrium critical point, at which point the highly symmetry-broken state looks rather “chaotic”: here the randomly distributed and tangled *purple lines* of variable lengths and orientations depict spontaneously generated defects in the form of highly excited vortices in a strongly turbulent state. Notice that the defects only emerge within an elliptical volume—consistent with the

Fig. 7 Schematic of entire condensate growth process during a driven cooling quench from an initial equilibrium thermal configuration: Shown are density isosurfaces of the most populated (Penrose–Onsager) mode based on numerical simulations of Eq. (15) for the parameters of a recent elongated 3D harmonic trap experiment of Lamporesi et al. (2013), Donadello et al. (2016), as discussed in Liu et al. (2018). After the characteristic Kibble–Zurek delay time of $\sim \hat{t}$, one sees the spontaneous emergence of a “turbulent” quasi-condensate state (green) containing a large number of spontaneously generated defects (shown in purple) whose density decreases as one moves away from the trap center: these tangled defects gradually decay to a small number of well-formed vortices which are rather long-lived and become trapped in the growing macroscopically occupied condensate mode. During such evolution, the relative weight of the dominant eigenvalue (compared to the next largest one) increases significantly, revealing clear evidence of the transition from a quasi-condensate exhibiting multiple equally likely populated modes (around $\hat{t}$) to a pure BEC (with one dominant eigenvalue) in the latter density snapshots, in which the relative volume occupied by the defects has significantly decreased.

Fig. 8 Numerical demonstration of the Kibble–Zurek scaling hypothesis revealing self-similar evolution for the parameters of Fig. 7 in terms of appropriately rescaled (i) zero-momentum mode occupation $f(k=0)$, and (ii) coherence length l_{coh} for a range of different τ_Q . Main plots show rescaled evolution of insets, with time measured in terms of $(t - t_c)$ (where $t_c = t(\epsilon = 0)$) and scaled to $\hat{t}$. Rescaled vertical axes respectively plot (i) $(\tau_0/\hat{t})f(k=0)$ (where τ_0 is a nonuniversal constant time) and (ii) $l_{coh}/\hat{\xi}$. In the unscaled insets (plotted in terms of $(t - t_c)$), the value of the quench timescale τ_Q decreases from the lower (slower quench, green) to the upper (faster quench, red) curves. imposed anisotropic harmonic confinement—and that the defect density is highest at the trap center, where the particle density is also highest: I will comment later on the significance of such observations.

Based on the Kibble–Zurek scaling hypothesis, all system observables become universal during the time interval $t \in [-\hat{t}, \hat{t}]$, thus uniquely specifying the temporal window during which one should be investigating universal Kibble–Zurek scaling effects for constant-rate cooling quenches $\tau_Q = T_c/|\dot{T}|$.

The emergence of such universal features can be seen in Fig. 8 which showcases the unscaled (insets) and appropriately rescaled dynamical evolution of (i) the zero-momentum mode occupation $f(k=0)$ [left], and (ii) the evolving system correlation length l_{coh} [right]. Unscaled images are plotted in terms of the time $(t - t_c)$ lapsed since crossing the equilibrium phase transition, whereas such shifted time has been additionally scaled by $\hat{t}$ in the rescaled plots [main plots]. Moreover, in the rescaled plots, the vertical-axis variables have been respectively rescaled as $\tau_0/\hat{t}f(k=0)$ and $l_{coh}/\hat{\xi}$. These simulations (Liu et al., 2020) reveal universal features up to a timescale of $\sim \hat{t}$ after the system crosses the equilibrium critical point. Although a delayed response was also found in more recent experiments with the same system, at such early times there was neither direct access to the spatially resolved density distribution nor the vortex number, with such delay instead attributed to other factors masking the ability to extract $\hat{t}$ directly (Wolswijk et al., 2022).

As the system is further cooled (i.e., $\epsilon > 0$ increases), one obtains a clear glimpse of its quasi-condensate characteristics: in particular, one sees the emergence of scattered localized regions of randomly selected near-constant phase (and so high coherence *locally*), separated by chaotically evolving and highly excited defects (vortices): at this stage there are many highly occupied modes competing against each other, and such information is revealed by the study of the largest, approximately equally dominant, eigenvalues (Liu et al., 2018)—providing direct evidence of quasi-condensation. The state of the system can also be thought of as “turbulent” (in the broad interpretation of the word).

As time evolves, and the system is further externally cooled (at the same constant rate), the random quasi-coherent regions grow in size, with the defects separating such regions interacting with other defects, thus dissipating their energy and shrinking in size. Naturally, the process of defect generation through the symmetry-breaking process and defect decay through coarsening coexist temporally, making it hard to isolate the relative importance of such competing mechanisms. However, at sufficiently late times after the dynamical phase transition crossing (i.e., for $\epsilon(t) \gg 0$), and within a specific temporal window, such dynamics are generally expected to exhibit a new set of self-similar (universal) scaling behavior associated with the phase-ordering process (Bray, 1994; Damle et al., 1996). The complicated inhomogeneous and anharmonic elongated 3D geometry of this system largely conceals such features, which are therefore discussed in more detail later on in the “cleaner” context of a homogeneous 2D quantum gas in Section “Scaling hypothesis and late-time coarsening.” The net effect of this lengthy process is the gradual establishment of domains of increased volume and coherence, and thus the gradual transition from a state of “quasi-condensation” to that of true condensation, with properties set by the external system parameters (T and μ).

During such dynamics, the tight transverse direction rapidly constrains the system evolution, and dictates the specific type of defect preferentially forming in such a system; this corresponds to the macroscopic excitation with the lowest energy in the given geometry (In this case, such defect is a so-called “solitonic vortex” which exhibits a 2π phase winding characteristic of quantized vorticity, but with a nonuniform gradient, such that its phase profile resembles the characteristic planar jump of a dark soliton from larger distances (Donadello et al., 2014).). As the defect density gradually decreases, one sees the emergence of a phase-coherent condensate within which are embedded few long-lived defects; this is in fact a very clear dynamical demonstration of the trapping of defects emerging as relics of the phase transition in the growing highly coherent system. The particular geometrical set-up constrains their interactions such that they only interact rather infrequently when few defects remain. However, when they do, the defects can reconnect and dissipate away further energy (Serafini et al., 2017). After significant such evolution, the system eventually expels all of its defects: at this point, the competition between the various quasi-condensate modes is complete, and one arrives at a fully

Fig. 9 Dependence of dynamical growth on quench rate for the parameters of Fig. 7 based on characteristic single-trajectory temporal evolution from a fixed initial (thermal) to a fixed final state (with a $\sim 75\%$ BEC fraction) for three different values of τ_Q : schematic at the top shows symmetric quench protocol from a $\mu < 0$, $T > T_c$ initial thermal state to one with $\mu > 0$, $T < T_c$ indicating corresponding temperatures and atom numbers characteristic of such controlled quench experiment. The quench rate increases from quasi-adiabatic (top) to fast (bottom), with middle trajectory showcasing a typical case where Kibble–Zurek scaling is expected to be fully applicable. Remarkably, faster quenches (bottom) contain (on average) more defects at a very late evolution time that slower quenches. Adapted with permission from Liu I-K, Donadello S, Lamporesi G, Ferrari G, Gou S-C, Dalfovo F, and Proukakis NP (2018) Dynamical equilibration across a quenched phase transition in a trapped quantum gas. *Communications Physics* 1(1): 24. phase-coherent Bose–Einstein condensate. Such a transition is further confirmed by a study of the ratio of the largest to second-largest eigenvalue of the system as a function of time (Liu et al., 2018, 2020). Density profiles (green) in Figs. 7 and 9 showcase the evolution of the spatial distribution of the most populated eigenstate, even though one only becomes genuinely dominant (the Penrose–Onsager mode) at late times.

Obviously, details of such process are heavily dependent on the quench protocol (e.g., temperature quench, interaction quench, geometry/phase-space quench), system geometry and dimensionality and interaction strength (which respectively set the typical number, type, and size of the defects). A characteristic illustration of how the quenching rate (which for given initial and final states is simply a function of the inverse quench timescale τ_Q) affects the dynamics can be found in Fig. 9, which displays the system evolution over an extended fixed total evolution time for three different quench rates (Liu et al., 2018). As evident, more defects are generated *on average* early on for more rapid quenches (bottom); moreover, because of this—and despite rapid defect annihilation and expulsion—typically more defects remain visible at a later absolute time when performing rapid cooling (i.e., for systems that cross the equilibrium critical point $\epsilon = 0$ faster), than in more gradual cooling schemes. For completeness, I note that while the example trajectories chosen to be displayed here are characteristic of the average behavior, each single cooling realization (for a fixed value of τ_Q) can lead to some variation in the number (and distribution) of generated defects; therefore, one needs to perform a number of distinct numerical/experimental realizations to appropriately extract relevant averaged parameters (e.g., defect number evolution).

Performing such averaging over different realizations, both experiments (Donadello et al., 2016) and simulations (Liu et al., 2018) found a power law decay in the defect number with τ_Q , with an exponent broadly consistent with the analytically predicted exponent α for this setting (del Campo and Zurek, 2014); while such features/measurements were only experimentally accessible at rather late evolution times, much exceeding $\hat{t}$, numerical simulations demonstrated that the actual overall scaling behavior was rather insensitive to evolution time; this is presumably because after defects have formed, they primarily propagate “freely” in the confining potentials for significant fractions of time, thus being rather long-lived; this is particularly true when the number of defects is not too large and they are spread over a large volume, as is the case for not-very-fast quenches. Importantly—and rather intuitively—such Kibble–Zurek scaling was not however seen for very fast quenches ($\tau_Q \sim O(\hat{t})$): this arises when the maximum number of defects that can be accommodated in the system volume (or the maximum number that can be experimentally, or numerically, detected) has been reached in a given geometry, thus giving rise to a plateau in the defect number for small τ_Q ; this was

clearly observed experimentally (at late times) (Donadello et al., 2016), and found to be consistent both with a simple model and with numerical simulations (Liu et al., 2018). We also note that the decay of fluctuations was found to obey a universal power law, with a distinct exponent to that corresponding to the growth of condensation (Liu et al., 2018; Wolswijk et al., 2022).

The quenching of defect number for very rapid quenches (i.e., the deviation from the Kibble–Zurek scaling law $n_{\text{defect}} \sim (\tau_Q)^{-\alpha}$) was also observed in strongly interacting fermionic superfluids (Ko et al., 2019) and in more recent bosonic experiments in an oblate geometry (Goo et al., 2021, 2022; Kim et al., 2022). The latter series of experiments also reported observational evidence for universal coarsening dynamics during the early stages of defect formation. Moreover, they were able to observe spatial variations in the generated defect number: both these features are in qualitative agreement with the presented numerical simulations (Liu et al., 2018).

All above features indicate that—rather unsurprisingly—there is more to driven phase transition crossing than the simple (but still very elegant and powerful) adiabatic-impulsive-adiabatic Kibble–Zurek model of Fig. 6. Below I address more systematic extensions of such a model, as highly relevant in light of such recent experimental developments.

Beyond homogeneous Kibble–Zurek considerations

The preceding discussion has highlighted two limitations of the adiabatic-impulsive-adiabatic Kibble–Zurek scenario of Fig. 6 which I address here.

The first one, concerns the “freezing” of the correlation length ξ during the entire evolution $t \in [-\hat{t}, \hat{t}]$, to a constant (time-independent) value corresponding to its instantaneous value at the time $-\hat{t}$ when symmetry-breaking occurs; in other words $\xi \rightarrow \hat{\xi} = \xi(\epsilon(-\hat{t}))$, which would imply a constant size of domains during $[-\hat{t}, \hat{t}]$, which is somewhat counter-intuitive. In fact, during such a temporal period, causality implies the existence of a characteristic velocity for the growth of correlations which—in this context—can be defined as (Dziarmaga et al., 1999; Zurek, 2009; Sadhukhan et al., 2020)

$$\hat{v} = \frac{\hat{\xi}}{\hat{t}}. \quad (25)$$

Given that the typical locally coherent regions grow with such a velocity even during $t \in [-\hat{t}, \hat{t}]$, the emerging effective size of domains at $\hat{t}$ is in fact larger than previously suggested, with $\xi(+\hat{t})$ typically a few times its corresponding value at $-\hat{t}$ (Sadhukhan et al., 2020); a schematic of such enhanced picture is shown in Fig. 10. Although such considerations evidently decrease the total number of spontaneously generated defects, rather remarkably they do not actually invalidate the previous arguments in terms of the existence of *scalings* of the defect number with quench timescale (Eq. 24), provided of course that the system inhomogeneity determining the shape of the region of increasing density is appropriately accounted for in the exponent α .

In this context, it should be noted that the “cartoon” Kibble–Zurek scenario discussed in Section “The Kibble–Zurek scaling law” (Fig. 6) was formulated for a homogeneous system and thus assumed that the system reacts, in a statistical sense, in the same way irrespective of which part of the system one looks at. However, as clearly visible from Fig. 7—and commented upon earlier—the density is highest at the center of a harmonically confined gas, implying that coherence grows from the trap center radially outwards. As a result, both the critical temperature of the system and hence the distance to criticality ϵ become position-dependent (Zurek, 2009; del Campo et al., 2011, 2013; del Campo and Zurek, 2014), that is, $T_c \rightarrow T_c(\mathbf{r})$ and $\epsilon(t) \rightarrow \epsilon(\mathbf{r}, t)$. A natural question then arises, as to the extent to which the previous “cartoon” picture holds under inhomogeneous trapping, and how to appropriately generalize this.

Fig. 10 Extended view of the Kibble–Zurek mechanism explicitly accounting for a sonic horizon propagation with a critical speed of $\hat{\xi}/\hat{t}$. Unlike the “cartoon” regime of impulsive dynamics for $t \in [-\hat{t}, \hat{t}]$ shown in Fig. 6, during which the correlation length is assumed to remain frozen to its value at $-\hat{t}$, this improved picture allows the “sonic cone” to grow during such time window by a constant rate set by the instantaneous slope of $\xi(-\hat{t})/\hat{t}$. As a result, the typical radius of the region over which broken symmetry emerges grows from $\hat{\xi}$ to few $\hat{\xi}$. Reprinted with permission from Sadhukhan D, Sinha A, Francuz A, Stefaniak J, Rams MM, Dziarmaga J, and Zurek WH (2020) Sonic horizons and causality in phase transition dynamics. *Physical Review B* 101: 144429. <https://doi.org/10.1103/PhysRevB.101.144429>. In the context of the homogeneous Gross–Pitaevskii equation (with repulsive interactions $g > 0$), symmetry-breaking is induced simultaneously across the entire system when the chemical potential transitions from negative values (corresponding to a purely thermal cloud) to positive values. Due to the presence of the trap, one can instead define an effective spatially dependent chemical potential $\mu(\mathbf{r}, t) = (\mu(t) - V(\mathbf{r}))$; thus outlining at any given time the region with $\mu(\mathbf{r}, t) > 0$ where symmetry-breaking takes place. Such region grows radially outwards from the trap center (here in an elliptical manner), thus defining a phase transition front which propagates in the system with a characteristic speed

$$v_F(\mathbf{r}) = \frac{T_c(0)}{\tau_Q} \left(\frac{dT_c(\mathbf{r})}{d\mathbf{r}} \right). \quad (26)$$

As such, the simultaneous emergence of symmetry breaking in a homogeneous system can be described in terms of an infinite phase transition front velocity v_F , and this is also (locally) the case at the center of a harmonic trap where local evolution mimics that of a homogeneous system. The extent to which the emerging symmetry-breaking features in the phase transition of a system have a global or a local character thus depends on the competition between the characteristic velocity $\hat{v}$ for the growth of correlations set by causality and the velocity v_F for the growth of the critical front as determined by the system geometry, thus also accounting for the shape of the growing volume of the coherent density front. The generalization of the Kibble–Zurek effect, which accounts for such spatial variations and local features, is known as the inhomogeneous Kibble–Zurek mechanism, and is extensively discussed in Zurek (2009), del Campo et al. (2011), del Campo et al. (2013), del Campo and Zurek (2014), Sadhukhan et al. (2020), and Dziarmaga et al. (1999).

As a result, the previously discussed “cartoon” picture of Section “The Kibble–Zurek scaling law,” known as the *homogeneous* Kibble–Zurek picture remains *qualitatively* valid as long as (and within the regions where)

$$v_F > \hat{v}, \quad (27)$$

that is, the growth of the critical front happens on a faster rate than such causality-induced coherence growth associated with the sonic horizon. In such a regime, the phase of each newly formed domain is chosen locally. As explained above, this is always the case in the center of the harmonic trap, and in a region near the propagating front (due to critical slowing down) (del Campo et al., 2013). As a result, defects can in general only form spontaneously over a restricted volume in an inhomogeneous system, thus leading to a reduced number of emerging defects in comparison to the homogeneous predictions. In the opposite limit of $v_F < \hat{v}$, the growing condensate can rapidly communicate its choice of phase to the neighboring domains, and so no further defect formation can occur. For an evolving system to enter a regime where it can probe its true inhomogeneous nature, the sonic horizon should be growing faster than the evolution of the critical front.

This, in turn, places constraints on the values of τ_Q required in a given system for a quench to allow the inhomogeneous nature of the phase transition to be fully probed; applying such simple arguments to the above elongated 3D experiment suggested the need for significantly slower quenches, thus also requiring longer evolution times and enhanced system stability. Although such a regime was not reached in the experiments of Donadello et al. (2016), it should nonetheless be noted that (i) the corresponding numerical simulations discussed in Section “Analyzing Kibble–Zurek in an elongated ultracold atomic system” clearly demonstrated the spatial dependence of spontaneous defect generation over a restricted volume, and that (ii) both observed and numerically computed scalings of the defect density with τ_Q were found to be consistent with predictions based on critical exponents for a harmonic trap (Donadello et al., 2016; Liu et al., 2018) (leading to an amended power $\alpha = (d - \mathcal{D})(1 + 2\nu)/(1 + \nu\mathcal{Z})$ (del Campo et al., 2011; del Campo and Zurek, 2014) when such geometrical features of the growth were taken into account).

Furthermore, it has been noted that a quasi-2D geometry may be a more favorable setting for observing such spatial signatures of the inhomogeneous nature of the dynamical phase transition. This was indeed shown in very recent experiments in a quasi-2D geometry; specifically, following experiments highlighting the anticipated importance of coarsening dynamics during the early stages of spontaneous defect formation (Goo et al., 2021, 2022) observations of the spatial distribution of defects in such a geometry found (after allowing the system to relax further and expand) a local suppression of spontaneous defect generation with τ_Q , which was more pronounced in the outer region (Kim et al., 2022). In other words, the local value of the power law exponent $\alpha(r)$ dictating the defect number through the power law $n_{\text{defect}} \sim \tau_Q^{-\alpha(r)}$ was inferred after expansion to increase locally as one moves away from the trap center. While such an observation is consistent with the interplay of causality and inhomogeneity, they consistently found higher exponents than might be anticipated. Although various factors could be at play here, associated with the fact that observations were made after relaxation and expansion (and so not at $\hat{t}$), the ongoing defect dynamics and coarsening, and intricate details of the trapping potential; this does also pose interesting questions meriting further investigation regarding the applicability of the inhomogeneous Kibble–Zurek effect.

Irrespective of the precise details just discussed of corrections to the basic Kibble–Zurek scheme, which allow for evolution of the characteristic lengthscale and the interplay between inhomogeneity and causality, as the system exits the critical region in the $\epsilon > 0$ side of the phase transition at $t = +\hat{t}$, it will be left in a rather nonequilibrium state (the faster the quench, the more nonequilibrium the state is likely to be—see Fig. 9); such a nonequilibrium state features a random mosaic of domains of different, near-constant, phase, separated by defects of variable length, orientation, and curvature, in a way which accounts for the differences in phase between the establishing micro-domains. The relaxation of such a state through the gradual decay of the number/length of defects will ultimately lead to the final coherent state for the given system parameters. Here, one can distinguish two cases: Either one continues driving the system to the final desired equilibrium and studies its relaxation in an “open” (driven) environment or one

leaves the system in such a highly chaotic/turbulent state and observes its dynamical evolution toward relaxation in a “closed” manner: the fundamental dynamics governing these two cases are different. Nonetheless, in both cases, universal laws can (and do, in general) emerge in certain temporal (and momentum) windows. Below I discuss the general concept of self-ordering by means of a scaling hypothesis, paying attention to nonequilibrium features, particularly in terms of universal late-time dynamics and other more general nonequilibrium features facilitating a bidirectional dynamic scaling, both of which can leave a significant imprint in the decay of superfluid turbulence.

Although very distinct dynamical regimes with different scaling laws, the dynamically evolving ξ discussed above does bear some notional analogy to the dynamically growing lengthscale $L_c(t)$ emerging in the scaling regime discussed below.

Universality during phase-ordering dynamics

So far, I have discussed the role of finite-duration quenches in a system, focusing on an incoherent to coherent thermal phase transition. We have discussed a broad dynamical range from quasi-adiabatic to near-instantaneous transitions, and explained how universal Kibble–Zurek dynamics emerges in the critical region provided the quench is not too fast. As discussed, the relaxation process in the system is governed by the decay of defects giving rise to growing regions of constant phase, with the quasi-condensate giving way to a macroscopic condensate (Witkowska et al., 2011; Liu et al., 2018), a process known as phase-ordering.

In order to present the key features of such process in its most pure form, it is convenient to consider the idealized limit of instantaneous quenches. Moreover, based on the above findings on the role of inhomogeneous trapping, and in order to suppress transversal (e.g., Kelvin-wave-like) excitations on the defects, I initially restrict the discussion to two-dimensional homogeneous systems, before returning to more general nonequilibrium settings.

Scaling hypothesis and late-time coarsening

The dynamics through which the system expels all defects and orders its phase is known as phase-ordering kinetics, and has a long history. Here I do not attempt to give a full account—referring the reader to excellent reviews (Bray, 1994; Rutenberg and Bray, 1995b, a)—but rather to discuss its features in the specific context of quenched quantum gases.

Naturally, even when quenched instantaneously, the system requires some time to order itself: as argued before, defects—which emerge at the interfaces across regions of different phases—gradually disappear, thus allowing adjacent regions of particular (randomly chosen) phases to merge, leading to the temporal growth of the typical domain size. A key point to note here is that this is also a scaling phenomenon. From a statistical point of view, the distribution of such domains—each with a constant phase, yet no phase coherence between them—looks at late times remarkably similar to the one at earlier times, with the growth of the typical domain size fully accommodated through a (simple) global change of scale.

We recall at this stage that a dynamical scaling hypothesis was previously considered in the context of the Kibble–Zurek scenario [Eq. (23), Section “The Kibble–Zurek scaling law”]. The scaling function was generally argued to change in time both in terms of its shape (through its explicit dependence on $t/\hat{t}$) and its spatial extent. In stark contrast to this, I note here that during the late-time self-similar dynamics and in the scaling limit $r \gg \xi$, the shape of the correlation function remains unchanged (i.e., there is no explicit dependence on time), with its spatial range changing in time only through a dynamically growing domain size $L_c(t)$, that is, through a dependence of the form $r/L_c(t)$; such an increase in the characteristic length scale is consistent with the number of independent domains and defect number decreasing.

The existence of a single (dynamical) dominant lengthscale in the system allows us to formulate the correlation function in the form (Bray, 1994)

$$C(\mathbf{r}, t) \sim F\left(\frac{r}{L_c(t)}\right) \quad (28)$$

with the corresponding momentum distributions taking the form

$$n(k, t) \sim [L_c(t)]^d G(kL_c(t)). \quad (29)$$

Here, F is an (unspecified) universal function and G is its Fourier transform, with temporal variation fully accounted for by the change in scale.

To calculate how such a characteristic lengthscale varies for a nonconserved field (i.e., in the presence of external dissipation), one can utilize energetic considerations, taking into account the system symmetries and the fact that the defects are not isolated (thus introducing a lengthscale beyond which a defect becomes screened by other defects). By estimating a critical velocity for the growth of such domains $u = dL_c(t)/dt$ and integrating, one can obtain the functional form of $L_c(t)$, as explicitly discussed in Bray (1994). This is generally found to exhibit a power law scaling of the form $L_c(t) \sim t^\beta$, with the critical exponent β related to the dynamical critical exponent z through $\beta = 1/z$. We note that in the special case of point vortices in a purely 2D geometry the presence of external dissipation (e.g., through coupling the system to an external bath) leads to well-known logarithmic corrections such that $L_c(t) \sim (t/\log(t))^{1/z}$.

The topic of phase-ordering has been extensively discussed in the literature (see, e.g., Yurke et al., 1993; Rutenberg and Bray, 1995a; Damle et al., 1996; Jelić and Cugliandolo, 2011; Nam et al., 2012; Karl and Gasenzer, 2017; Groszek et al., 2021). To make this point clear, I briefly discuss here recent extended numerical simulations (Groszek et al., 2021) in a 2D box with periodic boundary conditions in the context of both the conservative and the dissipative Gross–Pitaevskii equations, respectively via Eqs. (14) and (15).

In both cases, phase-ordering during the postquench evolution takes place through the annihilation of vortex-antivortex pairs (white/black squares in temporal evolution snapshots shown in Fig. 11A–C). Spatial correlations at a general time t are probed in terms of the equilibrium correlation function $g_{eq}^{(1)}(r, t)$ —the latter obtained after very lengthy numerical propagation—through the generic relation

$$\frac{g^{(1)}(\mathbf{r}, t)}{g_{eq}^{(1)}(\mathbf{r}, t)} = F\left(\frac{\mathbf{r}}{L_c(t)}\right). \quad (30)$$

Correlation functions in terms of the scaled time-dependent variable $\mathbf{r}/L_c(t)$ are found to collapse perfectly onto a single function (Fig. 11D) within a certain time window, which thus identifies both the evolutionary stage when the scaling hypothesis (Eq. 28) holds and the manner in which $L_c(t)$ grows, directly confirming an evolution of the form $L_c(t) \sim t^\beta$. Correspondingly, directly counting the decay in the vortex number, one confirms a scaling for the vortex density of the form $n_v \sim 1/L_c^2 \sim t^{-2\beta}$. Identifying $\beta = 1/z$ allows the extraction of the dynamical critical exponent z through these fits during the scaling interval. The behavior shown in Fig. 11 is generic, broadly applicable to both the conservative and the dissipative Gross–Pitaevskii equations.

Nonetheless, a detailed numerical comparison of the predictions between the conserved and dissipative regimes leads to slightly different behavior and modifications in the precise value of the critical exponent. This can be traced back to the fundamental question of “isolated” (conservative) vs. ‘open’ (dissipative) quantum systems (Hohenberg and Halperin, 1977); in the purely dissipative limit (i.e., Eq. (15) without the 1 in $(1 - i\gamma)$), the existence of vortices leads to logarithmic corrections to the system dynamics, such that $L_c(t) \sim (t/\log(t))^{1/z}$ with $z = 2$ exactly, and such behavior is explicitly reproduced in the simulations [see also subsequent discussion in the context of instantaneously quenched driven-dissipative exciton-polariton condensate systems (Section “Driven-dissipative condensation in exciton-polariton systems”)]. However, in the purely conservative limit (and without

Fig. 11 Phase-ordering kinetics of a 2D homogeneous Bose gas following an instantaneous quench across the BKT phase transition: (A)–(C) Evolutionary snapshots of the phase, showing the reduction in the number of vortices/antivortices (white/black squares respectively). (D) Self-similarity through the collapse (main plot) of the spatial correlation functions evaluated at different times t within the “collapse window,” scaled to $\hbar/\mu$ (inset) onto a universal scaling function F in terms of the scaled variable $r/L_c(t)$ according to Eq. (28). (E) Postquench growth of the characteristic lengthscale $L_c(t)$, clearly highlighting the time window when all self-similar correlation functions perfectly collapse onto one another. (F) Corresponding decreasing evolution of the vortex number density n_v . Although both (E) and (F) plot the variation across the entire temporal domain, note that the very late-time evolution is somewhat sensitive to numerical boundary effects (as can be seen from the slight deviation of both behaviors at very late times). including such logarithmic corrections), the value of z was found to lie approximately 15–20% below the $z = 2$ value (Groszek et al., 2021). While a possible explanation for such a change in z is likely to arise from a power-law vortex mobility due to vortex-sound interactions, a detailed understanding of such subtleties (as well as its extension to inhomogeneous systems) is still lacking.

Evolution around nonthermal fixed points

At this point, the reader is briefly reminded (in rather basic terms) of the notion of “fixed points” in renormalization group theory—for more details the reader is referred to Nishimori and Ortiz (2011), Binney et al. (1992), and Bruce and Wallace (1992). In such a language, one typically scales out microscopic details in favor of global features of macroscopic observables; as such, one deals with a parameter space of available many-body configurations of the system expressed in terms of a limiting set of relevant “coupling” parameters: long-time evolution between possible many-body system configurations is then modeled through flowing trajectories within such space, in a manner governed by the system Hamiltonian. Such a picture can be characterized by a small number of fixed points, which define the nature of the system evolution for different configurations. Specifically, flow around (toward/away from) such points qualitatively indicates the system evolution in parameter space. Naively, one can think of a fixed point as arising when a change of the scaling parameter, for example, $L_c(t)$, leaves the correlation function unchanged (Binney et al., 1992). For example, for a system undergoing a single-phase transition, one can directly identify certain fixed points: in the common case of a thermal phase transition, one identifies a low-temperature fixed point (denoting the system equilibrium at $T = 0$, e.g., in the fully coherent state, or more generally in the $\epsilon \rightarrow +\infty$ limit) and a high-temperature fixed point (denoting the system in the $T \rightarrow \infty$, or $\epsilon \rightarrow -\infty$ limit); ultimately the system flows to either of those, with all equilibria below/above the critical point formally mapping onto the former (condensed), or latter (thermal) by an appropriate rescaling of relevant parameters. Such trajectories are separated by a critical line/surface, which contains a “mixed” critical fixed point, such that it is attractive along all the directions within the critical surface, and repulsive along those pointing away from the critical surface (Binney et al., 1992). Note that exactly at the critical point, the system exhibits fluctuations at all lengthscales, making it impossible to eliminate (as argued above) short-scale behavior through a sequence of transformations, thus implying that a critical point is a fixed point. More generally, a fixed point is characterized by a pure scaling form and a coupling which no longer changes under a rescaling. The previously discussed phase-ordering dynamics is a simple example of a scaling phenomenon controlled by a (strong coupling) fixed point (Bray, 1994).

In general, various different classes of fixed points may exist. In particular, some attention is currently being devoted to the context of so-called ‘nonthermal’ fixed points, which arise as a fixed point in a typical far-from-equilibrium scenario: as such, they can be thought of as nonequilibrium configurations exhibiting scaling in both space and time, in terms of a limited number of properties. These were originally introduced by Berges and coworkers in the context of reheating after early-universe inflation (Berges et al., 2008; Berges and Hoffmeister, 2009; Piñeiro Orioli et al., 2015; Berges, 2016), and have been increasingly investigated across different physical systems, including heavy-ion collisions (Berges et al., 2015, 2021) and quantum gases (Nowak et al., 2011, 2012, 2014; Karl and Gasenzer, 2017; Chantesana et al., 2019; Schmied et al., 2019), also finding applications in a range of experiments (Prüfer et al., 2018; Erne et al., 2018; Glidden et al., 2021; García-Orozco et al., 2022; Madeira and Bagnato, 2022). The emergence of such points builds upon the concepts of self-similarity and critical behavior, generalizing them to far from equilibrium dynamics. Under appropriate conditions, a system may spend a significant amount of time around such a nonthermal fixed point. The discussion below is largely based on recent reviews (Chantesana et al., 2019; Schmied et al., 2019; Madeira and Bagnato, 2022).

In a nutshell, the dynamics of a system in the vicinity of a nonthermal fixed point acquires a generalized evolution according to

$$n(k, t) = \left(\frac{t}{t_0}\right)^\alpha n\left(\left(\frac{t}{t_0}\right)^\beta k, t_0\right), \quad (31)$$

where α and β are two scaling parameters which are, in general, distinct and which, combined, identify the universality class of the system. The relation between α and β is in fact set by the relevant conservation laws of the system. Essentially, these define—within a broad momentum range—how particles are redistributed in the self-similar regimes, and relate the scaling exponents α and β . In the simplest case of particle number conservation (and for a particle with quadratic dispersion relation), this leads to $\alpha = \beta d$ (in the long-wavelength, or infrared, regime), where d is the system dimensionality. Further noting that the characteristic lengthscale $L_c(t) \approx t^\beta$, and $\beta = 1/z$ practically reduces such expression to that of Eq. (29) governing the self-similar phase-ordering kinetics previously discussed. As such the preceding discussion of Section “Scaling hypothesis and late-time coarsening” can be seen as a special case of nonthermal fixed points under total particle number conservation.

However, the concept of nonthermal fixed points is more general. In particular, I note that the scaling function (Eq. 31) can behave differently in different momentum limits, namely, the previously discussed “inverse” particle transfer toward lower momenta arises from the conservation of particle number in the infrared (low-momentum) limit. Scalings due to energy conservation instead affect the ultraviolet (high-momentum) limit, leading to energy transport toward higher momenta and $\alpha = (d + z)\beta$. As a result, evolution around a nonthermal fixed point leads to a bidirectional flow (see Fig. 12).

As a highly nonequilibrium feature, it is not surprising that the potential emergence of a nonthermal fixed point following a thermal quench would require a rather specific engineered nonequilibrium set of initial conditions. In this context, I note the seminal numerical work of Berloff and Svistunov (2002). They considered a quench in a 3D box, starting with a strongly nonequilibrium initial condition (Svistunov, 1991; Kagan et al., 1992; Kagan and Svistunov, 1994, 1997) $\Phi(\mathbf{r}, t = 0) = \sum_k a_k e^{ik \cdot \mathbf{r}}$, for which the magnitudes of the complex amplitude a_k were obtained from the self-similar solution of the (wave/semiclassical)

Fig. 12 Schematic of the bidirectional flow exhibited by the spectrum $n(k, t)$ vs. k [shown here in terms of $p = \hbar k$] around a nonthermal fixed point: A highly nonequilibrium initial distribution with equal population across all modes up to a cutoff, and random phases—shown here by the *dashed red lines*—evolves in a manner such that particles flow in an inverse manner toward lower k (through conservation of particle number: $\alpha, \beta > 0$), while energy flows toward higher k ($\alpha, \beta < 0$), carried by few particles in a manner which conserves total system energy. Boltzmann equation describing the system dynamics sufficiently before the critical phase transition region, and their phases were uniformly distributed between 0 and 2π . Evolving by means of the classical field Eq. (14), they observed, as would be expected, particle build-up toward lower momenta, with most particles restricted to modes below a certain cutoff. This is a direct indication of the gradual build-up of a quasicondensate, arising from the macroscopic occupation of, and competition between, numerous low-momentum modes. Significantly, however, filtering out higher momentum modes revealed a tangle of vortices, a characteristic of a “strongly” turbulent state.

As the governing equation (Eq. 14) is conservative, this tangle was found to gradually decay, following the relaxation process of superfluid turbulence in a nondriven system through the generation of sound waves and shrinking/annihilation of defects via a typical energy cascade. Similar features, revealing also information about the vortex structure and its decay products, were found when doing a limited time averaging, thus connecting to the previous discussion on the application of short-time averaging during evolutionary dynamics (Section “Penrose–Onsager condensation vs. quasi-condensation”). We also note here that probing the state of an initially nonequilibrium system after very long classical field evolution in a separate numerical work revealed the existence of vortex tangles, with the total vortex linelength increasing significantly as the system energy, and thus temperature, was increased (Davis et al., 2002). Considering a similar scenario, Nowak et al. (2014) studied the system evolution following a sudden thermal quench by removing high-momentum particles from the distribution. When a relatively small amount of energy was removed through the quench, they also found the system to evolve toward a coherent condensate, with clear evidence of a tangle of vortices after filtering short-wavelength fluctuations. However, when a stronger quench was performed by instantaneously removing all the particles above some momentum cutoff value, they found a long-standing strong wave turbulence inverse cascade toward lower energies, with a rather distinct power law power spectrum $n(k) \sim k^{-5}$; such behavior, which is consistent with so-called “Porod” high-momentum tails $n(k) \sim 1/k^{d+2}$ (Schmied et al., 2019; Bray, 1994) corresponds to the case of randomly distributed vortices at momenta exceeding the inverse lengthscale corresponding to the distance between defects, a feature that is a direct consequence of the velocity field ($\mathbf{v} \sim (1/r) \hat{\phi}$) around a vortex line. Nonetheless, excitations in the high-momentum part of the spectrum still revealed $n(k) \sim k^{-2}$, leading to a bimodal spectrum. Importantly, the above-discussed features were now found to become observable without the need to filter out short-wavelength fluctuations. Ultimately, the overall momentum distribution takes the form $n(k) \sim k^{-2}$, leading to the relaxation of the system—but this now happens on a much longer timescale. This was considered as evidence of the system spending significant time around a nonthermal fixed point.

This example clearly shows the distinct features that a thermal phase transition can exhibit depending on the nature and details of the strength of the cooling quench, that is, in this case on the initial nonequilibrium conditions for the classical field evolution. Further evidence of the emergence and decay of the arising vortex tangle and properties of the order parameter were also discussed in Kobayashi and Cugliandolo (2016b), Kobayashi and Cugliandolo (2016a), and Stagg et al. (2016).

Dynamical properties of evolution consistent with Eq. (31) were recently observed in experiments in an isolated quench-cooled atomic gas (Glidden et al., 2021). By removing a significant fraction of the atoms and energy of a system initially just above the critical temperature and doing this process with interactions switched off, the experiment was able to generate a highly nonequilibrium state, and observe its relaxational dynamics, thus verifying the expected distinct scaling relations across the ultraviolet and infrared limits, corresponding to different conservation laws (Glidden et al., 2021) (see Fig. 13). Moreover, this experiment was also able to confirm the emergence of a quasicondensate in the early evolution stages, with the coherence across the system gradually growing to span the whole system, in a manner consistent with the system equilibrium for the given atom number and total energy.

For completeness, I note here that manifestations of evolution consistent with Eq. (31) have also been reported (prior to the above experiment) in a quasi-one-dimensional spin-1 BEC (Prüfer et al., 2018), and a single-component BEC (Erne et al., 2018) while also bearing close analogies to the inverse cascade evolutions observed in 2D experiments (Johnstone et al., 2019; Gauthier

Fig. 13 Experimental demonstration of bidirectional flow according to Eq. (31) in an isolated $d = 3$ ultracold atomic gas in a box quenched from just above the critical temperature to a highly nonequilibrium situation by removing significant fractions of atoms and energy such that the system ultimately relaxes to a state with an $\approx 40\%$ BEC fraction: The unscaled momentum distribution shown in (B) at different evolution times following the nonequilibrium quench is scaled differently in the limiting (A) infrared case (for which one finds $\alpha, \beta > 0$, with $\alpha/\beta \approx 3$, consistent with the condition $\alpha/\beta = d$ for particle-conserving transport), and (C) ultraviolet case (for which one finds $\alpha/\beta \approx 5$ with $\alpha, \beta < 0$ consistent with the prediction $\alpha/\beta = d + 2$ for energy-conserving transport). et al., 2019). We refer the reader to these works and excellent recent reviews on nonthermal fixed points—which also address in some detail the relation of nonthermal fixed points to weak-wave turbulence and strong turbulence (Schmied et al., 2019; Chantesana et al., 2019)—and their experimental study in ultracold quantum matter (Madeira and Bagnato, 2022).

Relation of quenched turbulence dynamics to “controlled” turbulence experiments

In this chapter, I have focused on the emergence of “turbulent” features through the instantaneous (Section “Universality during phase-ordering dynamics”) or driven (Section “Universality during phase transition crossing: The Kibble–Zurek scaling law”) cooling across a thermal phase transition, starting from an incoherent state, that is, quenching from $\epsilon < 0$ to $\epsilon > 0$, and studying the relaxation of the emerging nonequilibrium states generated, which typically include some type of vortex tangle. As well known (Tsatsos et al., 2016; Barenghi et al., 2014; Tsubota et al., 2017), an open, dynamically driven, system can reach a steady state under continuous driving, subject to a dissipation mechanism at a different scale from that where energy is being injected, thus acquiring a momentum spectrum exhibiting universal features in a certain “inertial” range. On the other hand, a closed turbulent nonequilibrium system will gradually see its vorticity decay in a manner which can also display universal scaling laws; for completeness, I briefly consider both these cases below.

First, if the system is left isolated shortly after its quench into such a turbulent state, one could also compare its subsequent relaxation evolution to studies characterizing the decay of superfluid turbulence. The topic of superfluid turbulence has a rich history (Barenghi et al., 2001; Vinen and Niemela, 2002), with an extensive body of literature on liquid helium supplemented by recent work on ultracold quantum gases which gives access to different lengthscales (Barenghi et al., 2014; Tsatsos et al., 2016; Tsubota et al., 2017). The relaxation dynamics can be different, depending on whether the system is primarily a superfluid, or has a significant (potentially dominant) thermal fraction.

Current studies, based on experimental observations (Walmsley and Golov, 2008; Bradley et al., 2006) and detailed numerical simulations (Baggaley et al., 2012; Barenghi et al., 2016), make a distinction between two types of superfluid turbulence at relatively low temperatures when a well-formed condensate exists (see also recent reviews (Barenghi et al., 2014; Tsatsos et al., 2016)). The most common form of turbulence discussed is that of Kolmogorov, or “quasi-classical” turbulence, which can exhibit (under continuous injection of energy) a cascade of kinetic energy from large to small eddies, thus giving rise to the well-known classical Kolmogorov spectrum $E_k \sim k^{-5/3}$ for $k \ll 1/l$ (where l is the typical intervortex spacing); this form of turbulence—which is thus a property of the motions at lengthscales larger than the intervortex spacing—is now understood to be associated with the existence of turbulent bundles of vortices. Once the injection of energy is discontinued, this leads to a total vortex linelength decay (characterizing the intensity of turbulence), which scales as $L_V \sim t^{-3/2}$.

On the other hand, some systems can exhibit a (potentially transient) turbulent state, somewhat similar to random flow, which is dominated by the presence of individual randomly oriented tangled vortices (with most of the energy contained in the intermediate scales): in such a regime, known as “ultraquantum,” or “Vinen” turbulence, the vortex linelength decays instead according to $L_V \sim t^{-1}$.

Early controlled low-temperature turbulence experiments with ultracold atoms focused on the generation of tangled vorticity through either shaking across two distinct axes (Henn et al., 2009) or intense periodic driving (Navon et al., 2016) in both cases starting from a $T \approx 0$ pure condensate. As such dynamics are generated by initiating the dynamical quenching from the coherent side, it is clearly a very distinct excitation process to the thermal quenches starting from an incoherent system discussed in this chapter. Among other findings, this has led to the observation of the expected power-law spectrum $n(k) \sim k^{-\gamma}$ in a box geometry, consistent with (Kolmogorov-Zakharov) weak-wave turbulence of compressible superfluids (Navon et al., 2016); further characterization of the flux of such a cascade through dissipation, has enabled the probing of the propagation of the cascade front in momentum space at both short- and long-time evolution (Navon et al., 2019); very recent experiments from the same group have also facilitated a direct measurement of the equation of state in experiments. The concept of reversibility was also probed in such quenches. Experiments in a box revealed that when such a turbulent system was left undriven for a significant period, it would reform into a near-pure condensate consistent with the initial state, that is, the process was found to be fully reversible (Navon et al., 2016).

Nonetheless, I also note here a recent related experiment (García-Orozco et al., 2022) studying the evolution of $n(k, t)$ from a nonequilibrium initial state generated by the application of a misaligned sinusoidally varying magnetic field on an initial highly coherent harmonically confined BEC. The excitation was performed in such a manner so as to perturb the system through dynamical rotations and distortions. Rather interestingly, such an experiment observed a behavior broadly consistent with the scaling relation of Eq. (31), but in this case both α and β exponents were found to be negative (beyond the expected $\alpha, \beta < 0$ values in the ultraviolet regime) also in the infrared regime: this should be contrasted to the previously discussed dynamics observed following a strong nonequilibrium quench in a box-like geometry (Glidden et al., 2021) for which in the infrared regime both $\alpha, \beta > 0$. For completeness, I mention also here related studies of such an inverse excitation process starting from a coherent equilibrium BEC and leading to a strongly nonequilibrium symmetric state, proceeding through a sequence of states with spontaneously arising topological defects: while this effect has been loosely named an “inverse Kibble–Zurek” scenario (Yukalov et al., 2015)—in the sense of dynamics in the opposite direction to the established (and previously discussed) Kibble–Zurek mechanism—this is simply a qualitative analogy, as no corresponding detailed scaling laws have been obtained.

Although a detailed understanding of all above dynamical issues is still an open matter, the ongoing experiments evidence the important role that an inhomogeneous geometry can play, and the richness of the dynamical features it can generate, which may have a nonnegligible impact on the types of turbulence generated and their subsequent relaxation. Moreover, differences in the dynamical properties of turbulent states generated starting from a well-formed superfluid, or an incoherent thermal cloud also highlight the important role that the thermal cloud can play on such dynamics.

For a more in-depth discussion of the current understanding of the relation between nonthermal fixed points, weak-wave turbulence and strong turbulence, and the relevance of such fixed points to other dynamical aspects, such as prethermalization (Berges et al., 2004; Gring et al., 2012), the reader is referred to the review articles (Schmied et al., 2019; Chantesana et al., 2019).

Selected further considerations

Beyond continuous single-component atomic gases

The properties of ultracold atomic gases can be controlled experimentally by a range of different tunable parameters. In this chapter, I have focused on the role of temperature in inducing a transition across criticality between two single-component thermalized states with very different characteristic properties. Relevant comments have also been made regarding the role of geometry and dimensionality in single atomic species confined in continuous potentials, such as harmonic traps and box-like potentials.

The exquisite control offered in experiments with ultracold atoms has opened up the way for a plethora of other types of quenches—with, no doubt, new physics yet to be explored in them, although significant progress toward various probes of universality have already been performed. While this section cannot do justice to such exciting developments, for completeness I note in passing a few such areas of relevance below.

A transition across criticality can also be engineered at fixed temperature by changing the interaction energy, which can also control the type of emerging equilibrium phase transition. In this vein, [Smith et al. \(2011\)](#) demonstrated the smooth crossover from an interaction-driven BKT transition to a BEC transition in the limit of vanishing interactions. Such issues are further discussed in [Smith \(2017\)](#). For example, the interaction energy can be tuned by changing either the atom number/density or the effective strength g of contact interactions appearing in the Gross–Pitaevskii equation—which provides another exciting knob for probing universal physics.

Moreover, one can also control the dominant type and range of interactions in dipolar atomic condensates, which offer tuneability in the relative strength of local and long-range interactions ([Chomaz et al., 2022](#)). Furthermore, degenerate Fermi gas settings provide an added “dimension” to such topics through control of the interaction strength, as they encompass different physical regimes depending on the value of $(k_F a)^{-1}$, where k_F is the Fermi wavevector and a the s-wave scattering length. In particular, such systems facilitate a study of the BEC limit (in the sense of atoms pairing up to form closely bound molecules which then Bose-condense), the BCS limit (where the formation of Cooper pairs of atoms in momentum space leads to familiar BCS-like effects), and—even more interestingly—the unitarity regime between these two, exhibiting infinite-range interactions. The physics of the unitarity limit is however also accessible in Bose gases. Moreover, the coexistence of mixtures of quantum-degenerate gases and components with a spin degree of freedom (or, so-called, spinor gases) enable such studies to be generalized to quantum mixtures.

In the vein of the main topics covered in this chapter, I note a significant (but not exhaustive) body of literature on Kibble–Zurek-type quenches, including, for example, through interaction-induced quenches in mixtures ([Sabbatini et al., 2011](#)) and spinor condensates ([Sadler et al., 2006](#); [Saito et al., 2007](#); [Świsłocki et al., 2013](#); [Witkowska et al., 2013](#); [Williamson and Blakie, 2016](#); [Anquez et al., 2016](#); [Jiménez-García et al., 2019](#)), prethermalization quenches in 1D ([Langen and Schmiedmayer, 2017](#); [Gring et al., 2012](#)), superfluid quenches across unitarity ([Eigen et al., 2018, 2017](#)), and quantum quenches ([Dziarmaga, 2010](#); [Polkovnikov et al., 2011](#)) in periodic potentials (optical lattices) ([Greiner et al., 2002](#); [Chen et al., 2011](#); [Braun et al., 2015](#); [Clark et al., 2016](#)), which could facilitate applications in quantum simulations ([Bloch et al., 2012](#); [Gardas et al., 2018](#); [Bando et al., 2020](#)), or in the presence of disorder ([Meldgin et al., 2016](#)), with open realms for studying Kibble–Zurek physics in systems such as dipolar gases and photon condensates. An important feature of quantum quenches is that they are performed under conditions of negligible thermal dissipation, thus potentially facilitating better control and cleaner scalings while allowing for the possibility of the emergence of new interesting physical regimes.

Clearly these, and other settings not mentioned here, demonstrate the power of controlled quantum gas experiments with ultracold atomic gases. Nonetheless, new physics corresponding to the dynamics in an open quantum system can be probed in another experimentally well-controlled quantum gas platform, namely that of exciton-polariton systems, which I discuss next.

Driven-dissipative condensation in exciton-polariton systems

A somewhat distinct physical system, that of exciton-polariton condensates, can be studied by embedding a 2D quantum well in a semiconductor microcavity driven by external pumping (laser) ([Deng et al., 2010](#)). The presence of the cavity allows the emergence of a new type of quasiparticle, which is a mixture of a photon and a matter excitation; under sufficiently strong pumping, this leads to “hybridization” and a new dressed-state bosonic quasiparticle whose spectrum facilitates the emergence of a quasi-ordered state with a high degree of coherence ([Kasprzak et al., 2006](#); [Carusotto and Ciuti, 2013](#); [Bloch et al., 2022](#)). As this is a strictly 2D system, technically one should not speak of “condensation,” but rather of a “BKT”-type phase transition to a “quasi-condensate” state exhibiting quasi-long-range order, as discussed in more detail below. Experimentally, there are various distinct pumping schemes that can be used to generate such an exciton-polariton system; one of these used rather commonly is that of incoherent pumping, which allows the quasi-ordered state to form spontaneously, through relaxation in the hybridized energy spectrum (relaxation in the so-called “lower polariton” branch).

Under the assumption that the exciton bath can be adiabatically eliminated—which is valid in many experimental set-ups—the fundamental equation describing such a scenario can take the form of a generalized Gross–Pitaevskii equation already alluded to in Section “Workhorse model of Bose–Einstein condensation” ([Wouters and Carusotto, 2007](#); [Keeling and Berloff, 2008](#)). When further adding stochastic noise to this (and in the usual convention of setting $\hbar = 1$), this takes the form of a stochastic complex Ginzburg–Landau equation ([Chiocchetta and Carusotto, 2013](#); [Carusotto and Ciuti, 2013](#); [Gladilin et al., 2014](#); [Comaron et al., 2018](#)):

$$i \frac{\partial \Phi}{\partial t} = -\frac{\nabla^2}{2m} + g|\Phi|^2 + \frac{i}{2} \left(\frac{P}{1 + |\Phi|^2/n_s} - \gamma \right) \Phi + dW \quad (32)$$

where m is the polariton mass (which is many orders of magnitude smaller than the electron mass), P is the strength of the homogeneous external drive, g is the polariton–polariton interaction strength, n_s is a (phenomenological) saturation density, and dW a complex-valued noise term satisfying $\langle dW^*(\mathbf{r}, t) dW(\mathbf{r}', t) \rangle = [(P + \gamma)/2] \delta_{\mathbf{r}, \mathbf{r}'}$, where γ here is the inverse of the polariton lifetime.

I note here that, despite the decaying nature of the quasiparticle, the system does nonetheless enter a nonequilibrium steady-state (provided external pumping is maintained). Different variants of this equation exist in the literature, including extensions that account for a frequency-selective pumping mechanism favoring relaxation to low-energy modes (Chiocchetta and Carusotto, 2013; Wouters et al., 2010; Comaron et al., 2018).

For such systems, the control parameter is not temperature, but pumping; in fact the quasi-coherent regime sets in when pumping exceeds a threshold “critical pumping” value. In other words, $\epsilon = (P - P_c)/P_c$ such that $\epsilon > 0$ occurs in the high pumping limit $P > P_c$ (recall that in the case of cold quantum matter $\epsilon > 0$ labeling the coherent side is a low-temperature case $T < T_c$). In the mean-field limit, when $\epsilon > 0$, Eq. (32) supports a nontrivial steady-state solution in the form of $|\Phi|^2 = n_s(P/\gamma - 1)$.

Based on the previous discussion, one would expect a BKT transition associated with vortex–antivortex binding with increasing pumping strength; however the driven-dissipative nature of the system can modify such picture of “equilibrium condensation” previously discussed in the context of ultracold atomic gases (For the sake of clarity, I note here that while ultracold atomic condensates can be thought of as equilibrium, that is, fully-relaxed, during their probed long timescale, the true thermodynamic equilibrium of such systems is in fact a solid, facilitated by three-body loss processes which are not usually dominant during experimentally-probed timescales in most cold atom settings, thus enabling “long” lifetimes of up to a few minutes), and this has led to significant discussion in the community about the nature of the phase transition (Altman et al., 2015; Dagvadorj et al., 2015; Keeling et al., 2017).

In effect, the extent that the phase transition from disordered to (quasi-)ordered state is an “equilibrium” phase transition or not—and the nature of the arising correlation functions on the quasi-ordered state—depend on the system parameters, which can be controlled by the quality of the sample on which experiments are performed (i.e., the polariton lifetime), but also by the spatial pump profile, details of the pumping scheme, and any engineered anisotropy in the effective polariton mass. Depending on such parameters, these systems can also exhibit a broader range of universal behavior, as discussed below.

We start with revisiting the universal dynamics during a gradual driven transition (Kibble–Zurek) and the late-time phase-ordering for parameters corresponding to recent exciton-polariton experiments (Nitsche et al., 2014). The equilibrium criticality phase diagram can be characterized by looking at the divergence of the characteristic coherence length, ξ on the incoherent (here below threshold) pumping side $\epsilon < 0$ and the corresponding behavior of the exponent α_s of the spatial coherence power law decay on the $\epsilon > 0$ (quasi)ordered side (Eq. (10) with $\alpha(T) \rightarrow \alpha_s$). Such behavior is shown in Fig. 14A as a function of the ratio of the pumping power to the corresponding critical value predicted by mean-field theory (respectively by green and red lines) (Comaron et al., 2021). First, it should be noted here that due to the inclusion of fluctuations (via the noise term), the transition is in fact shifted from the predicted mean-field value by a few %. It is instructive to also consider the decay of the temporal correlations as one approaches the critical region from the $\epsilon > 0$ (quasi-)ordered side; these are shown by the red line. The diverging behavior on the (quasi)ordered side is the same qualitatively for spatial and temporal correlations. However, it clearly becomes evident (see also inset) that $\alpha_s = 2\alpha_t$ (Comaron et al., 2021), with such a relation between their respective exponents giving the transition a genuine nonequilibrium flavor (Szymańska et al., 2006, 2007). Moreover, various experiments observed the universal scaling exponent characteristic of the spatial correlation function decay on the (quasi)ordered side to exceed the expected equilibrium value of $(1/4)$ at the critical point (Roumpos et al., 2012; Nitsche et al., 2014); although this has also been seen in numerical simulations (Dagvadorj et al., 2015), the results presented here—while broadly consistent with such a picture—cannot provide a conclusive answer because the precise value is also expected to be somewhat sensitive to finite-size effects (Comaron et al., 2021).

Having identified the precise location of the critical point, one can now consider the dependence of the system properties as a function of the distance to criticality ϵ , the first step toward performing and characterizing linear quenches across the phase transition. As expected the number of vortices in this 2D system at equilibrium decreases very dramatically in the vicinity of $\epsilon = 0$ (dashed red line in Fig. 14B). Quenching across the transition at different rates leads to such vortices surviving for significant amounts of time after the system parameters have been quenched to the (quasi-)ordered side (Zamora et al., 2020); this is here visible by the slower decay of vortices with ϵ , where $\epsilon = \epsilon(t) = t/\tau_Q$ following the quenched system evolution through the externally imposed parameter. The slower decay of vortices in time as the system adapts to the external quench across the phase transition leads to the expected divergence in the relaxation time (red line, $\tau(\epsilon)$, in bottom left inset to Fig. 14B). The faster one quenches across the phase transition (i.e., the smaller that τ_Q is), the deeper into $\epsilon(t) > 0$ values that the vortices can be observed on the (quasi)ordered side. Of course, ultimately such vortices will decay to the corresponding equilibrium value at such value of ϵ , marked by the dashed red line. I recall here that the quench rate affects the slope of $\epsilon(t)/\dot{\epsilon}(t)$ (dashed blue line in bottom left inset to Fig. 14B), and so the exact location of the intersection point of these two curves which, according to the fundamental Kibble–Zurek equation, defines the timescale $-\hat{t}$. Numerical simulations (Zamora et al., 2020) have confirmed the validity of the Kibble–Zurek scenario, by revealing the expected proportionality between the observed relaxation time of vortex dynamics (essentially the time when the quenched solid lines in Fig. 14B deviate from the equilibrium dashed red line) and the time predicted by matching $\tau(-\hat{t})$ to $\epsilon(-\hat{t})/\dot{\epsilon}(-\hat{t})$ (up to some irrelevant microscopic nonuniversal prefactor); such proportionality can be seen in the top right inset.

In the long-time limit, the vortices decay. As discussed in Section “Scaling hypothesis and late-time coarsening,” this decay (following instantaneous quenching into the (quasi-)ordered state) is expected to enter another scaling window, associated with phase-ordering (Jelić and Cugliandolo, 2011). Already from Fig. 14B one can see that the vortex decay slows down as their number decreases for a given value of τ_Q , that is, along a particular curve shown in Fig. 14B. This is because vortices move (on average) further and further apart; thus the frequency of their annihilations slows down. Then, at some late time, when there are only relatively few vortices left in the system, the behavior changes drastically. Such behavior (following now an instantaneous quench) has been mapped out in Fig. 14C; after a very rapid decay in the number of vortices (blue) and corresponding increase in the

Fig. 14 Universal features of a nonequilibrium driven-dissipative exciton-polariton condensate for typical experimental parameters. (A) Dependence of the coherence length, ξ , defined by $g^{(1)}(\mathbf{r}) \sim e^{-r/\xi}$ on the incoherent side of the phase transition, and of the spatial (temporal) exponents α_s (α_t) defined on the quasi-ordered side by $g^{(1)}(\mathbf{r}) = r^{-\alpha_s}$ ($g^{(1)}(t) = t^{-\alpha_t}$). Horizontal axis depicts the external pump power in units of the critical value predicted by mean-field theory, with the transition occurring above the critical pump threshold (here $P_{cr} \sim 1.033$); fluctuations clearly shift this by (up to) a few %, toward a higher pump value. *Inset*: zoomed-in version clearly revealing $\alpha_s = 2\alpha_t$ as direct evidence of the nonequilibrium nature of the phase transition in such parameter regime. (B) Demonstration of validity of the Kibble–Zurek relation (Eq. 19). Main panel shows the dependence of vortex number on $\epsilon = (P - P_0)/P_c$ for the equilibrium case (dashed red line) and the corresponding dependence for $\langle N_v(t) \rangle$ in terms of $\epsilon(t)$ for a linear external quench in the pump via $\epsilon(t) = t/\tau_0$, with τ_0 decreasing between curves as one moves from left to right. For each τ_0 , there is a corresponding value of $\epsilon = \epsilon(\hat{t}_{num})$ at which the (dynamical) curve determining the postquench number of vortices (solid) as a function of ϵ deviates from the corresponding equilibrium one (dashed red)—these values are shown by the dashed vertical lines, and yield the numerical estimate $\hat{t}_{num}$. *Insets*: (bottom left) Relation between diverging relaxation time τ and characteristic timescale $\epsilon(t)/\epsilon(t)$ in the vicinity of the critical point, with their intersection defining the freeze-out time $-\hat{t}_{KZ}$. (top right) Demonstration of $|\hat{t}_{num}| \sim |\hat{t}_{KZ}|$ validating the expected Kibble–Zurek proportionality relation (up to some microscopic, nonuniversal prefactor). (C) Evolution of decreasing number of vortices/antivortices (blue curve) and growing characteristic lengthscale (green curve) highlighting the dramatic early postquench coarsening evolution, and their corresponding dependence on time in the scaling regime, allowing us to extract the dynamical critical exponent $z = 2$. Note that all axes are plotted on logarithmic scale, with the temporal axis also including the anticipated logarithmic correction to the system evolution. characteristic lengthscale describing the typical size of the emerging quasi-ordered regions (green), the system enters the scaling regime (Comaron et al., 2018). In this regime, properties of the system can be characterized by a single growing lengthscale and thus all correlation functions collapse onto a single function, in terms of such an appropriately rescaled variable $L_c(t)$ (see Eq. 30). Interestingly, one now sees very clearly both the existence of the expected logarithmic corrections in the presence of external coupling (dissipation) (previously discussed in Section “Scaling hypothesis and late-time coarsening”), and the anticipated value of the dynamical critical exponent ($z = 2$) (Jelić and Cugliandolo, 2011). While this behavior is expected to continue at later times, finite size effects make it harder to obtain concrete predictions of $L_c(t)$ from the spatial correlation function.

The above results have painted the picture of a “nonequilibrium” BKT phase transition, and an anticipated late-time phase-ordering law, with significant discussion in the literature addressing the nature of this phase transition (Dagvadorj et al., 2015; Altman et al., 2015; Keeling et al., 2017). Parallel to this, there has been quite some interest in searching for a different kind of universal behavior on the quasi-ordered ($\epsilon > 0$) side of the transition, associated with a so-called Kardar–Parisi–Zhang (KPZ) universality class (Kardar et al., 1986).

The KPZ equation describes the stochastic growth of the height of an interface and is established in diverse (classical) physical settings, including, for example, polymer growth, and spreading of wildfires. In the present context, I note that the KPZ equation arises as an equation modeling the phase of the superfluid θ , obtained from $\Phi(\mathbf{r}, t) = \sqrt{n(\mathbf{r}, t)}e^{i\theta(\mathbf{r}, t)}$ in the presence of a momentum-dependent damping rate under the assumption that the density fluctuations ($\delta n(\mathbf{r}, t) = n(\mathbf{r}, t) - \langle n(\mathbf{r}, t) \rangle$) vary slowly both in space ($\nabla \delta n \approx 0$) and in time ($\partial n / \partial t \approx 0$). Such an assumption makes the KPZ physics more relevant in regimes characterized by weak-phase fluctuations, namely, deep in the quasi-ordered phase $\epsilon > 0$. In that case, one obtains the KPZ equation in the form (Altman et al., 2015; Gladilin et al., 2014; Ji et al., 2015; Wachtel et al., 2016; He et al., 2015; Squizzato et al., 2018; Deligiannis et al., 2021)

$$\frac{\partial \theta}{\partial t} = v \nabla^2 \theta + \frac{\lambda}{2} (\nabla \theta)^2 + \sqrt{D} \eta. \quad (33)$$

The terms on the right-hand side describe the diffusion leading to smoothening, a nonlinear contribution leading to critical roughening, and a stochastic noise term, with the constants v , λ , and D depending on microscopic system parameters. This equation maps the evolution of the phase of the polariton mean field to a growing interface with the same internal dimension.

Let us consider the general normalized first-order correlation functions in space and time in the form $g^{(1)}(\mathbf{r}, \mathbf{r} + \Delta \mathbf{r}, t, t + \Delta t)$ and denote this by the short-hand notation $g^{(1)}(\Delta \mathbf{r}, \Delta t)$. In general (upon neglecting density–density and density–phase correlations), one can show that (Fontaine et al., 2022)

$$g^{(1)}(\Delta \mathbf{r}, \Delta t) = \langle \exp(i\Delta \theta(\Delta \mathbf{r}, \Delta t)) \rangle \quad (34)$$

where $\Delta \theta$ denotes the change in phase from some reference value. To lowest order in the fluctuations, this would thus give the dominant behavior that

$$\begin{aligned} \text{Fixed } \Delta t_0 : |g^{(1)}(\Delta \mathbf{r}, \Delta t_0)| &\sim \exp\left(-\frac{1}{2}\left(\frac{\Delta r}{\lambda}\right)^{2\chi}\right) \\ \text{Fixed } \Delta r_0 : |g^{(1)}(\Delta \mathbf{r}_0, \Delta t)| &\sim \exp\left(-\frac{1}{2}\left(\frac{\Delta t}{\tau}\right)^{2\beta}\right) \end{aligned} \quad (35)$$

thus introducing the two KPZ critical exponents χ and β for space and time, respectively, denoting the roughness and growth critical exponents (with λ and τ , the corresponding nonuniversal parameters). As a result, KPZ scaling would show up as “stretched exponential” decay in the correlation functions in the limit of a relatively well-formed mean field, that is, for “sufficiently large” $\epsilon > 0$ values (such behavior is termed “stretched exponential” here because $2\chi, 2\beta \neq 1$ as would be the case in a “normal” exponential). In order to unequivocally observe such behavior, one would generally need to observe very large systems (and for very long times) because of the existence of a characteristic minimum lengthscale for the onset of KPZ physics (Altman et al., 2015).

Notwithstanding the earlier comments about a possible *nonequilibrium* BKT phase transition, an experiment conducted with high-quality samples (and so longer polariton lifetimes, thus facilitating a less nonequilibrium regime) found two interesting results (Caputo et al., 2018) (see Fig. 15A); first, although spatial and temporal correlation functions could be fitted by both stretched exponential and power-law decays in the vicinity of the critical region, the power-law decay always fits better on the quasi-ordered side of the phase transition, thus explicitly verifying BKT-type correlations—consistent with BKT being the transition mechanism. Second, unlike the previous discussion, the power-law exponents for the spatial and temporal decay on the quasi-ordered side were found to exactly match each other, both having a value clearly below 0.25. All this corroborated to an *equilibrium* BKT phase transition in this particular experimental setting, demonstrating that exciton-polariton condensates can control the extent of the “equilibrium” or “nonequilibrium” nature of the phase transition through the sample quality characterizing the polariton lifetime.

From a theoretical point of view, the universal scaling function for KPZ takes the form (Deligiannis et al., 2021)

$$\begin{aligned} C(\Delta \mathbf{r}, \Delta t) &= \langle (\Delta \theta(\Delta \mathbf{r}, \Delta t))^2 \rangle - \langle \Delta \theta(\Delta \mathbf{r}, \Delta t) \rangle^2 \\ &= -2 \ln(|g^{(1)}(\Delta \mathbf{r}, \Delta t)|) \\ &= C_0(\Delta t)^{2\beta} F\left(\gamma_0 \frac{|\Delta \mathbf{r}|}{\Delta t^{1/z}}\right), \end{aligned} \quad (36)$$

where $F(\gamma)$ is a universal scaling function (whose asymptotics are known), $z = \chi/\beta$ and C_0 and γ_0 are nonuniversal constants.

Such emergence of KPZ scaling was conclusively demonstrated in an appropriately engineered (discrete) 1D setting (Fontaine et al., 2022), constituting the first realization of KPZ scaling in a quantum system. In addition to identifying a spatial/temporal region where Eqs. (35) hold (Fig. 15B(i)–(ii)), they were able to convincingly demonstrate the emergence of a universal spatiotemporal KPZ scaling function by plotting $C(\Delta \mathbf{r}, \Delta t)/(\Delta t)^{2\beta}$ as a function of $\Delta r/\Delta t^{1/z}$, for the particular exponent values of $\beta = 1/3$ and $z = 3/2$, thus corresponding to $\chi = 1/2$.

Extending such analysis to the 2D limit, the same team also managed to numerically demonstrate—sufficiently above threshold so that vortices do not overwhelm KPZ effects (Deligiannis et al., 2022)—the emergence of scaling according to Eq. (35), with critical exponents consistent with those anticipated in the 2D KPZ universality class. This opens up the possibility of observing—for the first time—2D KPZ physics in an experiment, a long-standing goal in nonequilibrium statistical physics. The above brief discussion highlights driven-dissipative exciton-polaritons as ideal systems for tuning both the extent of equilibrium (or nonequilibrium) nature of the BKT phase transition, and the prevailing universality class through carefully engineered experiments (Zamora et al., 2017; Diessel et al., 2022).

Fig. 15 (A) Regime of 2D equilibrium BKT. Dependence of the spatial and temporal correlation function exponents as a function of the pumping (here d) scaled to the critical value (d_{BKT}) for the experimental parameters of Caputo et al. (2018). Depicted values correspond to exponents labeling correlation decay in the form of either stretched exponentials (left part of plot) or algebraic decay (right part of plot) according to which one of these fits works best in each regime. Here one sees clearly that algebraic decay (characteristic of the 2D XY model) dominates (overstretched exponential decay) for all points above threshold, and that, importantly, the emerging spatial (α) and temporal (β) exponents are equal and do not exceed the value of 0.25 at the critical point. (B) and (C) Experimental demonstration of nonequilibrium KPZ scaling in 1D. (B)(i)–(ii) Identification of spatiotemporal regime where both spatial and temporal correlations exhibit their expected stretched exponential scalings of Eq. (35) on the quasi-ordered side. (C) Appropriately rescaled plot confirming the KPZ picture of Eq. (36) for all data points in (B)(i)–(ii) within the corresponding scaling regimes for which $|g^{(1)}|$ takes the values shown within the annulus in the bottom right inset. Note that such scaling function shows a plateau at small $y = y_0 \Delta t / (\Delta t)^{2/3}$ and linear growth at large y . Bose–Einstein condensation on astrophysical/cosmological scales?

Due to its universal nature, BEC has even been hypothesized to be at play across very different astrophysical/cosmological settings. Perhaps the most broadly known example is that of neutron stars (Pethick et al., 2017), whose core is expected to exhibit both superfluidity and superconductivity. However, various other forms of condensation have been discussed in the literature (see, e.g., early discussions in Griffin et al., 1995), including rather interestingly condensation of gravitons (Dvali and Gomez, 2017). Below I briefly outline an alternative idea gaining increasing attention currently in the literature in the context of dark matter modeling.

The possibility of the existence of a cosmological-scale gravitating BEC of axionic particles has been proposed as a plausible alternative picture of the nature of dark matter (Hu et al., 2000) (see also the related scenario of thermalizing QCD axions (Banik

and Sikivie, 2017)). More recently, the focus of such theoretical ideas appears to be in the context of ultralight axion-like particles of mass 10^{-22} eV/ c^2 : due to their low mass, these can give rise to galactic-size de Broglie wavelengths (recall that $\lambda \sim 1/\sqrt{m}$), thus facilitating condensation on such unprecedented scales. While such systems cannot be controlled in any way (and so the question of phase transition crossing becomes less relevant), nonetheless, predictions of such models in the current (late-time, virialized) state could ultimately be related to cosmological observations.

As well known, there is currently an established model of cold dark matter (CDM), which explains the large-scale structures of the universe very well through N-body numerical simulations (Frenk and White, 2012). Nonetheless, some discrepancies have been recently noted in relation to the small-scale structure (Weinberg et al., 2015; Bullock and Boylan-Kolchin, 2017; Del Popolo and Le Delliou, 2017) (most notably the inferred distribution of the dark matter density at the very center of galaxies). One very elegant way (but admittedly not the only one) to resolve such discrepancies is to describe such features through BEC in the context of the so-called FDM model (Schive et al., 2014; Mocz et al., 2017; Marsh, 2016; Hui, 2021; Ferreira, 2021). The underlying idea here is that dark matter consists of ultralight axionic particles, of mass 10^{-22} eV/ c^2 . Due to their high density and low mass, such particles would have a very high phase-space density allowing the emergence of BEC on galactic scales. The power of such an approach is that it describes “short-range” (on cosmological scales) features by the emergence of a so-called gravitationally self-bound soliton of dark matter while still reproducing the very successful large-scale predictions of the usual CDM model—most notably the Navarro-Frenk-White (NFW) radial density profiles at large distances from the galactic core (Navarro et al., 1996).

The equation governing such cosmological condensates is a Schrödinger equation, embedded within the gravitational field (Widrow and Kaiser, 1993; Seidel and Suen, 1990; Schive et al., 2014; Mocz et al., 2017). In general, one could also envisage the existence of interactions between such axionic particles (although some constraints on their maximum strength do exist) (Chavanis, 2011; Desjacques et al., 2018; Mocz et al., 2023; Delgado and Muñoz Mateo, 2022), giving rise to the following system of coupled equations, loosely termed the Gross–Pitaevskii–Poisson equations:

$$i\hbar \frac{\partial \Phi(\mathbf{r}, t)}{\partial t} = \left[-\frac{\hbar^2 \nabla^2}{2m} + g\rho(\mathbf{r}, t) + mV(\mathbf{r}, t) \right] \Phi(\mathbf{r}, t) \quad (37)$$

where the Newtonian potential $V(\mathbf{r}, t)$ follows the Poisson equation,

$$\nabla^2 V(\mathbf{r}, t) = 4\pi G(\rho(\mathbf{r}, t) - \bar{\rho}) \quad (38)$$

with the mass density $\rho(\mathbf{r}, t) = |\Phi(\mathbf{r}, t)|^2$, and $\bar{\rho}$ its spatially averaged constant value (and G denotes the gravitational constant). (Interestingly this same set of equations has also been recently used to model glitches in pulsars (Verma et al., 2022).)

While the validity of the FDM model has yet to be tested, even in the absence of interactions (and we may still be a long way away before some of the emerging predictions can be directly tested against observational data), there is a rapidly growing body of work (see, e.g., recent reviews (Marsh, 2016; Hui, 2021; Ferreira, 2021)) addressing the model’s predictions both on the cosmological large scale (Fig. 16A) (Schive et al., 2014; Mocz et al., 2017; May and Springel, 2021) and on the level of a single (isolated) cored-halo regime corresponding to the distribution of dark matter on the level of a typical galaxy (Fig. 16B and C) (Mocz et al., 2017; Schwabe et al., 2016; Chan et al., 2022; Liu et al., 2023). The important new contribution from the FDM picture discussed in the above works (and many references therein) is that the density at the center of the galaxy behaves very differently to CDM predictions, with the emergence of a well-formed soliton whose density remains finite as $r \rightarrow 0$. Essentially this leads to a bimodal profile of a central soliton surrounded by fluctuating dark matter density satisfying the NFW profile; this is somewhat reminiscent of the density profiles of ultracold atomic gases in harmonic traps, with gravitational attraction in the galactic case playing a role analogous to the harmonic confinement of ultracold atomic gases—such an important and interesting analogy has been explicitly discussed in Liu et al. (2023).

Addressing the coherent properties of such a (virialized) cored-halo system, Liu et al. (2023) demonstrated that the discussed solitonic core is in fact fully coherent in the sense of a dominant Penrose–Onsager mode, with a nearly constant spatial correlation function in the central solitonic region exhibiting $g^{(1)}(\mathbf{r}) \approx g^{(2)}(\mathbf{r}) \approx 1$ for $r \lesssim r_c$, where r_c labels a typical soliton radius. Beyond this, there is an intermediate region of gradually decreasing coherence spatially, with global-phase coherence across the soliton core lost between the soliton core and an outer “transition” region r_t , at which point $g^{(1)}(\mathbf{r}) \approx 0$ and $g^{(2)}(\mathbf{r}) \approx 2$, consistent with a chaotic field. Nonetheless, closer inspection demonstrates that the outer halo region ($r > r_t$) contains randomly distributed regions of near constant density, which locally feature enhanced phase coherence. Such domains are separated by randomly oriented vortices that scramble the phase between them; in the cosmological context, such regions are termed “granules.” Such a picture closely resembles a cosmological-size quasi-condensate, as shown schematically—based on actual numerical data—in Fig. 16C (Liu et al., 2023); as such vortices are randomly oriented/distributed and move around (albeit on rather cosmologically-slow timescales), there is no overall phase coherence after radial, or temporal averaging. Moreover—at least in the absence of self-interactions—this system exhibits familiar scaling laws of (ultra)quantum turbulence, with such states in fact rather similar qualitatively to the early dynamical phases of condensate formation discussed in Section “Analyzing Kibble–Zurek in an elongated ultracold atomic system” (Liu et al., 2023); interestingly recent works have shown such a structure to be very long-lived, unlike the rapidly decaying turbulent states generated in nondriven ultracold atomic systems.

The predictions of the FDM model may end up not having a direct bearing on real-world observables. Nonetheless, the mere fact that a cosmological model of a BEC can actually generate features seemingly consistent with our current understanding of large-scale structure in the universe is truly remarkable in its own right, and demonstrates the power and universality of such a physical phenomenon.

Fig. 16 Cosmological condensation in the fuzzy dark matter (FDM) model (also known as ψ DM in Schive et al. (2014)): (A) Large-scale comparison of FDM predictions (left) to the established cold dark matter (CDM) model based on N-body simulations (right) from a given set of initial cosmological conditions; large-scale features are excellently reproduced. (B) FDM simulations focusing on an isolated (single) galactic halo, which in the FDM model contains a characteristic solitonic core at its center (left image), reveal a number of interesting features shown in the right image; first, the radial density profile (black line) both exhibits a core at the center (unlike the CDM model predictions that lead to an “unphysical” $1/r$ divergence as $r \rightarrow 0$, which is not shown here) and reproduces the expected NFW profiles (dashed brown line) at larger distances ($r > r_t$); importantly, the solitonic core exhibits near-perfect coherence $g^{(1)}(r) \approx g^{(2)}(r) \approx 1$ for $r \leq r_c$, with coherence only gradually lost with increasing radial distance up to r_b at which point the NFW density profile sets in; in fact, the solitonic core can be fully described as a Penrose–Onsager condensate mode (green line) all the way up to r_b with the remaining (incoherent) density concentrated primarily outside the solitonic region, but with a nonzero (albeit small) component still present at smaller radii; this is directly analogous to the condensate–thermal cloud bimodal distribution of Hartree–Fock theories for ultracold atomic gases (see, e.g., Proukakis and Jackson, 2008) and the corresponding experimentally obtained density distributions. (C) Example schematic of the density distribution of the solitonic core (yellow core—with both r_c and r_t radii shown to give a sense of scale) surrounded by regions of decreasing density filled with random vortices (purple lines) which scramble the phase between different domains of locally similar phase—constituting a galactic-size example of a quasi-condensate state. Conclusion

In this chapter, I have given a broad overview of manifestations of macroscopic coherence across a diverse range of physical systems, spanning from the very tiny (exciton-polaritons, atoms) to the very large (cosmological). While the specific physical manifestation across such systems might be different, with BEC associated with a single macroscopic observable and off-diagonal long-range order giving way—in some limits—to related behavior in terms of a Berezinskii–Kosterlitz–Thouless transition to a quasi-ordered state, or even to a state exhibiting stretched exponential correlation functions consistent with those of the Kardar–Parisi–Zhang model over a restricted spatiotemporal regime, such systems nonetheless exhibit evidence of universal behavior in appropriate temporal domains and/or spatial regions, with some common observable features. This facilitates an exciting cross-fertilization of ideas, which have borne out of seemingly distinct fields such as low-temperature physics; statistical physics; condensed matter; and atomic, molecular, and optical physics. Interestingly, many of the ideas discussed in this chapter have their origins in cosmological or theoretical physics studies, even if perhaps some of those features are now becoming more the playground of controlled quantum matter experiments.

For example, the concept of defects arising during a dynamical phase transition becoming embedded into, and thus observable within, the long-time evolution of the system—first proposed in the context of a hot Big Bang model—has not only found significant validation in a diverse range of coherent quantum systems but also led to exciting studies pushing new frontiers in quantum gas experiments conducted with an unprecedented flexibility and accuracy—such as experiments with ultracold atoms. In this context, one is now investigating the modifications to this Kibble–Zurek scenario of driven quenching across the phase transitions imposed by inhomogeneities and the interplay with causality.

Moreover, the concept of highly nonequilibrium scenarios, associated with the dynamics around nonthermal fixed points emerged initially from studies of reheating after early universe inflation, but recent years have seen a number of distinct experiments with ultracold atoms revealing evidence of dynamics consistent with predicted scalings around such nonthermal-fixed points. Such nonequilibrium scenarios have a close connection with the emergence of (strong) turbulence, in a generalized manner, that is, with the state of a system filled with random tangled defects, which can also exhibit various types of universal scaling laws in appropriate regimes. Beyond the familiar and already observed direct energy cascade Kolmogorov turbulence of a driven system and associated decay of bundles of vortices once driving is removed, experiments with liquid helium and ultracold atomic systems have revealed a new “type” of turbulence, known as “ultraquantum” (or “Vinen”) turbulence, which is dominated by the tangling and relaxation of individual vortices. The rapid quenching of a phase transition creates a strongly “turbulent” state with broadly similar features qualitatively, whose subsequent evolution ultimately follows universal scaling laws—whether in the context of spatially self-similar solutions during phase-ordering, the stronger spatiotemporal evolution around nonthermal-fixed points, or even evolution related to the Kardar–Parisi–Zhang spatiotemporal self-similarity. Interestingly, such features also connect the driven or instantaneous breaking of a continuous symmetry with phenomena investigated in fluids, including classical fluids and growth of interfaces.

As such, systems exhibiting macroscopic quantum coherence in controlled quantum matter experiments give access to a range of different universal types of behaviors, and the emergence of a range of scaling laws having wide applicability to very different physical systems across both the classical and the quantum realm. Combined with the enhanced quantum control in these systems, which facilitates the on-demand construction of system Hamiltonians—thus making them ideal systems for quantum simulations—such systems collectively open up a very exciting, highly interdisciplinary realm for a deeper understanding of the nonequilibrium physical world.

Acknowledgments

The unified presentation given here has been made possible through collaborations (or extended discussions) on these topics with many excellent colleagues and friends over a period of years, including specifically for the presented context and concepts Tom Billam, Tom Bland, Jerome Beugnon, Iacopo Carusotto, Paolo Comaron, Leticia Cugliandolo, Franco Dalfovo, Jacek Dziarmaga, Jean Dalibard, Piotr Deuar, Gabriele Ferrari, Andrew Groszek, Giacomo Lamporesi, Fabrizio Larcher, Rob Smith, Henk Stoof, Marzena Szymanska, and Alex Zamora, to whom I am grateful. In such a context, I would particularly like to highlight Dr I-Kang (Gary) Liu and Dr Paolo Comaron who have been pivotal to my respective understanding of Kibble–Zurek physics and polariton condensation, as well as Dr Gerasimos Rigopoulos and Dr I-Kang Liu for our recent collaboration into coherent cosmological endeavors. During the preparation of this chapter, I have benefited enormously from discussions with, and direct feedback on this manuscript from, Vanderlei Bagnato, Carlo Barenghi, Paolo Comaron, Jacek Dziarmaga, Thomas Gasenzer, Gary Liu, Gerasimos Rigopoulos, and Marzena Szymanska. I also thank Jacek Dziarmaga, Thomas Gasenzer, Anna Minguzzi, Hsi-Yu Schive, Rob Smith, and Wojciech Zurek for explicit permissions to reprint key figures from their earlier works, and the UK EPSRC, Leverhulme Trust, and the Horizon-2020 framework for funding—with particular note to the Quanterra grant “Nonequilibrium dynamics in Atomic systems for QUAntum Simulation” (NAQUAS) which refocused my interest on such topics.

Abstract

We provide an overview of the effects of interactions in Bose-condensed gases. We focus on phenomena that have been explored in ultracold atom experiments, covering both tuneable contact interactions and dipolar interactions. Our discussion includes: modifications to the ground state and excitation spectrum, critical behavior near the Bose–Einstein condensation temperature, the unitary regime where the interactions are as strong as allowed by quantum mechanics, quantum droplets in mixtures, and supersolids in dipolar gases.

Key objectives

- Summarize ideal-gas Bose–Einstein condensation.
- Review the consequences of weak repulsive contact interactions on the ground state, excitations, and thermodynamics of Bose condensed gases.
- Showcase recent work on the unitary Bose gas.
- Highlight novel effects in condensates that experience attractive or dipolar interactions, including the formation of quantum droplets and supersolids.

Introduction

Bose–Einstein condensation (BEC) plays an important role across a variety of quantum systems and phenomena, from superconductivity (Onnes, 1911), and exciton (Deng et al., 2002, 2006; Kasprzak et al., 2006; Balili et al., 2007) and magnon (Demokritov et al., 2006) condensation in the solid state, to superfluidity in liquid helium (Kapitza, 1938; Allen and Misener, 1938), to photon condensates in optically pumped dye-filled microcavities (Klaers et al., 2010), and to its most direct demonstration in ultracold dilute gases (Anderson et al., 1995; Davis et al., 1995). A unique aspect of the Bose condensed state is that the (phase) order it displays is not primarily the result of interparticle interactions, but can occur in an ideal (noninteracting) gas solely due to quantum statistics.

In this article we discuss how the interplay of interparticle interactions with the underlying phase order affects the Bose-condensed state, and the host of fascinating phenomena that ensue. While such questions first arose in the context of liquid helium (a strongly interacting fluid), here we focus our discussion on dilute ultracold atomic gases. In these systems the interaction strength can readily be tuned, allowing controlled access to both subtle and dramatic interaction effects. This enables tests of fundamental many-body theories and the progressive exploration toward strong interactions, where a first principles description is intractable.

We further restrict our discussion to continuous Bose gases in three dimensions (3D), leaving aside fermionic systems where BEC can occur as a consequence of pairing (Inguscio et al., 2007; Zwerger, 2011; Zwierlein, 2014), Bose gases confined in optical lattices (Bloch, 2005; Morsch and Oberthaler, 2006), and lower-dimensional systems where the enhanced role of fluctuations often precludes BEC (Cazalilla et al., 2011; Hadzibabic and Dalibard, 2011). Note that we provide only a brief overview here; many of the topics are covered in much greater detail elsewhere (see, e.g., Pethick and Smith, 2002; Pitaevskii and Stringari, 2016). We also refer the reader to

other related articles within this volume; Stringari (2023) gives a more general introduction to BEC in ultracold atom systems, and while here we focus mainly on equilibrium systems Proukakis (2023) explores non-equilibrium effects on BEC formation.

The article is organized as follows. In “Noninteracting Bose gases” we briefly review Bose–Einstein condensation in a gas of noninteracting particles, before exploring the effect of different interparticle interactions on the Bose condensed state: “Weak repulsive contact interactions” and “Unitary contact interactions” consider repulsive contact interactions in, respectively, the weak and strong limit. “Attractive contact interactions and dipolar interactions” explores phenomena which occur due to either attractive or dipole-dipole interactions. Finally, we conclude and provide a brief outlook in “Conclusion.”

Noninteracting Bose gases

BEC is a phase transition associated with the onset of long-range phase order, which results from the macroscopic occupation of a single-particle state. This is a consequence of Bose–Einstein statistics and occurs at a critical temperature T_c far above the single-particle energy-level spacing.

Qualitatively, the transition can be understood by considering lengthscales in a quantum gas (see Fig. 1(a)). The two relevant lengthscales are the interparticle spacing, $n^{-1/3}$, set by the gas density n , and the (quantum-mechanical) thermal wavelength $\lambda = [2\pi\hbar^2/(mk_B T)]^{1/2}$ set by the temperature T and the mass m of the gas particles. Condensation occurs when the thermal wavelength is large enough to be comparable to the interparticle spacing ($\lambda \gtrsim n^{-1/3}$).

More quantitatively, we consider the occupation of a momentum state $\mathbf{p}$ in a homogeneous ideal (noninteracting) gas, which is given by the Bose distribution

$$f_B = \frac{1}{e^{(\varepsilon - \mu)/(k_B T)} - 1}, \quad (1)$$

where μ is the chemical potential and $\varepsilon = p^2/(2m)$ the energy of the state. The total number of particles in the gas is found by summing over all possible states:

$$N = \sum_{\varepsilon} \frac{g_{\varepsilon}}{e^{(\varepsilon - \mu)/(k_B T)} - 1}, \quad (2)$$

where the degeneracy factor g_{ε} accounts for the number of states with a given ε . Demanding all terms in the sum to be real positive numbers requires $\mu \leq \varepsilon_0$, where ε_0 is the ground-state energy. As μ approaches ε_0 from below (practically achieved by, e.g., increasing N) the ground-state occupation can become arbitrarily large (see Eq. (1)), whereas the occupation of all the other states (the excited states) sums to a finite (critical) number in 3D. This statistical saturation of excited states (graphically demonstrated in Fig. 1(b)) is, in essence, the mechanism for BEC. At fixed temperature, as particles are added to a Bose gas they populate the excited states until their population saturates at the critical atom number. From this point on, any additional particles must enter the ground state, which thus becomes macroscopically occupied.

In the thermodynamic limit, in which both N and the volume of the system V are large, while the particle density n is finite, we may (semiclassically) approximate the sum over excited states by an integral. The density of excited states n' (also known as the thermal density), is given by:

$$n' = \int \frac{d\mathbf{p}}{(2\pi\hbar)^3} \frac{1}{e^{(p^2/(2m) - \mu)/(k_B T)} - 1} = \frac{g_{3/2}(e^{\mu/(k_B T)})}{\lambda^3}, \quad (3)$$

Fig. 1 Ideal Bose gases. (a) Noninteracting ultracold Bose gases feature two relevant lengthscales: the interparticle spacing $n^{-1/3}$ and the thermal wavelength λ . (b) Excited- and ground-state phase space densities vs. total phase space density. Above a critical D_c (dotted vertical line), $n'\lambda^3$ saturates and $n_0\lambda^3$ grows. (c) Condensed fraction n_0/n vs. T/T_c (Eq. (5)).

where the polylogarithm $g_{3/2}(x) = \sum_{l=1}^{\infty} x^l / l^{3/2}$. We can re-express this result in terms of the phase space density $n'\lambda^3 = g_{3/2}(e^{\mu/(k_B T)})$, which reaches a maximum (critical) value when $\mu = 0$ (which is allowed as $\varepsilon_0 \rightarrow 0$), such that, $n'\lambda^3 = \mathcal{D}_c = g_{3/2}(1) \equiv \zeta(3/2) \approx 2.612$, where ζ is the Riemann function.

For a fixed n , the BEC transition temperature is given by

$$k_B T_c = \frac{2\pi\hbar^2}{m} \left(\frac{n}{\zeta(3/2)} \right)^{2/3}, \quad (4)$$

and the condensed fraction

$$n_0/n = 1 - (T/T_c)^{3/2}, \quad (5)$$

where n_0 is the condensate density (see Fig. 1(c)).

In the following section we discuss how this picture changes in the presence of weak repulsive *contact* interactions, a regime readily accessible in ultracold-gas experiments.

Weak repulsive contact interactions

For a dilute atomic gas the effective low-energy interaction between two atoms at $\mathbf{r}$ and $\mathbf{r}'$ can be approximated as a contact interaction $g\delta(\mathbf{r} - \mathbf{r}')$ with $g = 4\pi\hbar^2 a/m$, where a is the s -wave scattering length. The interactions are thus quantified by a single lengthscale a , which can be tuned experimentally using so-called Feshbach resonances (Chin et al., 2010). The consequences of interactions are often grouped into mean-field (MF) and beyond-mean-field (BMF) effects.

Simplistically speaking, MF effects result from the effective potential felt by a particle due to the average local particle density. Within the Hartree–Fock approximation (Dalfovo et al., 1999) the excited-state atoms feel an effective potential $V_{\text{int}}' = g(2n_0 + 2n')$ and, owing to the lack of the exchange interaction for particles in the same state, the ground-state atoms experience a different interaction potential $V_{\text{int},0} = g(n_0 + 2n')$. In a homogeneous system, these interaction potentials lead to a uniform energy offset, i.e., $\varepsilon = p^2/2m + V_{\text{int}}$ in Eq. (1). This is accompanied by a simple shift of the chemical potential such that it is only the factor of two difference between the condensate-condensate and condensate-thermal interaction potentials that leads to non-trivial interaction effects at the MF level. By contrast, in inhomogeneous systems the entire interaction potential is important as it effectively modifies the form of the trap. This often results in MF effects being more prominent in inhomogeneous systems; see Smith (2017) for a detailed discussion. Note that, at the MF level, the condensate behavior can be described by a macroscopic wavefunction that obeys the Gross–Pitaevski equation (see Pitaevskii and Stringari, 2016), a nonlinear Schrödinger equation.

Beyond-mean-field effects arise due to changes of the many-body wavefunction, sometimes referred to as quantum fluctuations. These effects become significant if the interaction energy $\sim gn$ is no longer negligible compared to the relevant (kinetic) energy. In particular, significant effects occur whenever low-energy (long-wavelength) excitations play a central role.

We now consider the effect of interactions on the elementary excitations of a Bose-condensed system, on its ground state, and on its behavior near T_c .

Excitations and sound

In a homogeneous system, at the MF-level the excitation spectrum is simply given by $\varepsilon(k) = p^2/(2m) + V_{\text{int}}' - V_{\text{int},0} = \hbar^2 k^2/(2m) + gn_0$, where $k = p/\hbar$ is the excitation wavenumber.

For low-energy (low- k) excitations this MF approach is no longer adequate; to next order the effect of interactions can be calculated using the Bogoliubov transformation (Bogoliubov, 1947), which enables a description in terms of noninteracting quasi-particles; this approach predicts an excitation spectrum

$$\varepsilon(k) = \sqrt{\frac{\hbar^2 k^2}{2m} \left(\frac{\hbar^2 k^2}{2m} + 2gn \right)}. \quad (6)$$

Now at low- k there are collective excitations with a sound-like form $\varepsilon/\hbar = c_0 k$, where $c_0 = \sqrt{gn/m}$. This is crucial for superfluidity in Bose condensed systems, as it ensures (unlike in an ideal gas) a nonzero superfluid critical velocity (according to the Landau criterion). The sound-like excitation spectrum was first seen in liquid ^4He (Nozières and Pines, 1990). In ultracold atomic gases, following initial studies of collective excitations (Jin et al., 1996; Mewes et al., 1996; Andrews et al., 1997), a direct comparison to Eq. (6) was made possible by using Bragg spectroscopy on an ultracold Bose–Einstein condensate (see Steinhauer et al., 2002; Kozuma et al., 1999; Stenger et al., 1999 and Fig. 2(a)).

At finite temperature the situation is further complicated by the presence of thermal excitations, which lead to two distinct sound modes, the (faster) first and (slower) second sound. The two modes can be understood, in the hydrodynamic limit, within the two-fluid model (Landau, 1941), which separately considers the normal and superfluid components. The nature of the sound modes changes depending on how compressible the Bose fluid is. In the almost incompressible liquid helium, first and second sound are, respectively, density and temperature (or entropy) waves. Instead, in a dilute Bose fluid (which is highly compressible) the two modes are excitations of mainly the normal and superfluid components (see Hilker et al., 2022 and Fig. 2(b)).

Quantized vortices are another important type of excitation that feature in interacting Bose-condensed gases. Such vortices carry angular momentum quantized in units of $\hbar/m$ and have vanishing density along the vortex core over a healing length $1/\sqrt{8\pi n a}$ (see Madison et al., 2000 and Fig. 2(c)). In a system containing many vortices the interactions between them can result in the

Fig. 2 Excitations in interacting degenerate Bose gases. (a) Excitation spectrum of a weakly interacting Bose–Einstein condensate, measured in a harmonic trap (Steinhauer et al., 2002). The solid line shows the fitted Bogoliubov form, with a linear spectrum at low momenta (dotted line), the slope of which gives the speed of sound. (b) At finite temperature a Bose fluid supports two sound modes, here measured in a box-trapped ultracold gas (Hilker et al., 2022); the speeds are normalized by the Bogoliubov speed and the solid lines show the two-fluid model predictions. (c) Vortices are another important type of excitation; the image shows a single vortex generated via stirring a Bose–Einstein condensate with a laser beam (Madison et al., 2000). (d) When large numbers of vortices are generated the interactions between them lead to the formation of an Abrikosov lattice (Abo-Shaeer et al., 2001). Panels adapted from: (a) Steinhauer, R Ozeri, N Katz, and N Davidson (2002) Excitation spectrum of a Bose–Einstein condensate, *Physical Review Letters* 88:120407, (b) Hilker, LH Dogra, C Eigen, JAP Glidden, RP Smith, and Z Hadzibabic (2022) First and second sound in a compressible 3D Bose fluid, *Physical Review Letters* 128:223601, (c) Madison, F Chevy, W Wohlleben, and J Dalibard (2000) Vortex formation in a stirred Bose–Einstein condensate, *Physical Review Letters* 84:806, (d) Abo-Shaeer, C Raman, JM Vogels, and W Ketterle (2001) Observation of vortex lattices in Bose–Einstein condensates, *Science* 292:476.

formation of vortex lattices (see Abo-Shaeer et al., 2001 and Fig. 2(d)). Note that these lattices are closely related to those that occur in type-II superconductors in the presence of a magnetic field; rotation can be thought of as an artificial magnetic field, which is an example of a synthetic gauge field (see, e.g., Goldman et al., 2014; Zhai, 2015; Aidelsburger et al., 2018).

Quantum depletion

In addition to modifying the excitation spectrum, interparticle interactions also modify the ground state, an effect known as quantum depletion. This entails the coherent expulsion of particles from the single particle ($p = 0$) ground state, even at $T = 0$; in essence, it is energetically favorable for some higher momentum states to be occupied.

The most striking example of quantum depletion occurs in liquid ^4He , where even though at $T = 0$ the system is 100% superfluid, the condensed fraction n_0/n is only around 10%. However, liquid ^4He is a strongly interacting fluid, and so theoretical predictions are challenging. Instead, for a weakly interacting gas $[(na^3)^{1/2} \ll 1]$, a theoretical description is more tractable, with $T = 0$ Bogoliubov theory predicting (Lee et al., 1957)

$$\frac{n_0}{n} = 1 - \frac{8}{3\sqrt{\pi}} (na^3)^{1/2}. \quad (7)$$

This famous prediction was experimentally verified in a box-trapped (homogeneous) ultracold gas (see Lopes et al., 2017 and Fig. 3). Within the same theoretical framework, the ground-state energy is also modified, as first measured by Navon et al. (2011).

Fig. 3 Measurement of quantum depletion. The maximal diffracted fraction η vs. the interaction parameter $(na^3)^{1/2}$; here a Bragg filtering technique was used to spatially separate the condensate from the high- k components of the gas (including the quantum depletion; see top inset). Assuming both perfect k -space separation and filtering, η corresponds to the condensed fraction. A linear fit (solid line) gives a slope $\gamma = 1.5(2)$, quantitatively confirming the Bogoliubov prediction $\gamma = 8/(3\pi^{1/2}) \approx 1.5$. The fact that the intercept is only close to unity, arises from an imperfect k -space separation and a non-zero initial temperature. The cartoon (bottom inset) depicts the coherent excitations out of the (blue) condensate, which occur as pairs of atoms with opposite momenta. Figure adapted from Lopes, C Eigen, N Navon, D Clément, RP Smith, and Z Hadzibabic (2017) Quantum depletion of a homogeneous Bose–Einstein condensate, *Physical Review Letters* 119:190404.

Interaction effects near T_c

We now turn to the effect of interactions on the thermodynamics of a Bose condensed gas, focusing on the behavior close to T_c ; these effects are summarized in Figs. 4(a, b).

First, in the (partially) condensed phase, interactions cause $n'\lambda^3$ to no longer be saturated at $\mathcal{D}_c$ (cf. Figs. 1(b) and 4(a)), but instead it decreases for increasing $n\lambda^3$. This effect comes about (at the MF level) because an atom can reduce its interaction energy by entering the condensate. Note that for a harmonically trapped gas the opposite effect occurs, with the excited-state population increasing as the system goes more deeply into the condensed state (Tammuz et al., 2011).

Secondly, condensation occurs at $\mathcal{D}_c < \mathcal{D}_c^0$ (or equivalently for $T_c > T_c^0$ at fixed n); here the superscript 0 denotes the ideal-gas results. This effect can only be understood at the BMF level, as long-wavelength fluctuations become increasingly important close to T_c . Calculating the shift was a significant theoretical challenge and it took several decades to reach a consensus (see Andersen, 2004; Arnold and Moore, 2001; Baym et al., 2001; Holzmann et al., 2004 for a review); the shift is predicted to be (Arnold and Moore, 2001; Kashurnikov et al., 2001)

$$\frac{\Delta T_c}{T_c^0} \approx 1.8 \frac{a}{\lambda}, \quad (8)$$

but this result has yet to be confirmed experimentally.

In a harmonic trap, a relatively simple geometric (MF) effect results in a negative T_c shift, with the more interesting BMF effects expected to be pushed to higher order in a/λ . As shown in Fig. 4(c), measurements in a harmonic trap (Smith et al., 2011) did show an upward shift from the MF prediction (dashed line), but making a quantitative comparison with Eq. (8) (dotted line) was not possible.

Thirdly, interactions modify the critical exponents of the BEC transition, changing the universality class to that of the 3D XY model. In particular, the correlation length critical exponent is predicted to change from $\nu = 1$ to $\nu \approx 0.67$ (Burovski et al., 2006a); see Fig. 4(b). This exponent has been measured by locally probing a harmonically trapped ultracold gas (see Donner et al., 2007 and Fig. 4(d)), and also with much higher precision in ^4He (see Burovski et al., 2006b).

Fig. 4 Thermodynamics near T_c . In (a) and (b) we illustrate the effects of interactions near T_c in a homogeneous system, while (c) and (d) highlight related experimental results. (a) Excited- and ground-state phase-space densities as a function of the total phase-space density for an interacting Bose gas (cf. Fig. 1(b)). For $n\lambda^3 > \mathcal{D}_c$, $n'\lambda^3$ is no longer saturated at $\mathcal{D}_c$, but decreases as $n\lambda^3$ increases. The critical phase-space density also undergoes a small shift. (b) The correlation length ξ vs. reduced temperature $t = (T - T_c)/T_c$ near the BEC transition. The interacting Bose gas is in the 3D XY Model universality class, which has $\xi \sim t^{-\nu}$ with $\nu \approx 0.67$. (c) Measured T_c shift vs. interaction strength for a harmonically trapped Bose gas Smith et al. (2011); an upward shift from the predominant MF geometric effect (dashed line) is seen, but quantitatively comparing this to the homogeneous system result (dotted line) was not possible. (d) Measurement of the correlation length critical exponent in a ultracold Bose gas Donner et al. (2007); the line is a fit to the data, which gives $\nu = 0.67(13)$ consistent with the 3D XY Model. Panels adapted from: (c) Smith, RLD Campbell, N Tammuz, and Z Hadzibabic (2011) Effects of interactions on the critical temperature of a trapped Bose gas, *Physical Review Letters* 106:250403, (d) Donner, S Ritter, T Bourdel, A Ottl, M Köhl, and T Esslinger (2007) Critical behavior of a trapped interacting Bose gas, *Science* 315:1556.

Unitary contact interactions

Here we consider Bose-condensed systems in the strongly interacting limit ($na^3 \gg 1$), experimentally accessible at a Feshbach resonance, where a diverges. In this so-called unitary regime, the interactions between particles are as strong as allowed by quantum mechanics. The fact that the value of the diverging a can no longer matter leads to the universality hypothesis, in which the interparticle spacing $n^{-1/3}$ is the only relevant lengthscale for a degenerate gas (see Cowell et al., 2002, Ho, 2004 and Fig. 5(a)). This also sets the natural momentum, energy, and time scales:

$$\hbar k_n = \hbar(6\pi^2 n)^{1/3}, E_n = \hbar^2 k_n^2 / (2m), \text{ and } t_n = \hbar / E_n. \quad (9)$$

In contrast to their widely studied Fermi counterparts (Inguscio et al., 2007; Zwerger, 2011; Zwierlein, 2014), unitary Bose gases feature dramatically enhanced particle loss¹ and associated heating, which makes their study an inherently dynamical problem and raised the question whether such a gas can ever exist in equilibrium.

The experimental approach has been to forsake equilibrium and quench into the unitary regime (by rapidly increasing a), to then observe the ensuing dynamics. These experiments have shown a remarkable degree of universality (see Makotyn et al., 2014, Eigen et al., 2017, 2018, Klauss et al., 2017 and Fig. 5(b, c)). The post-quench dynamics also revealed that the gas, even though it is not in true thermal equilibrium, does attain a quasi-equilibrium (prethermal) state (Berges et al., 2004; Makotyn et al., 2014; Yin and Radzihovsky, 2016; Eigen et al., 2018). Eventually, the gas decays and heats, ultimately following the dimensionless loss rate for a thermal unitary gas $-t_n \dot{n} / n \propto (E_n/E)^2$, where E is the kinetic energy per particle (dashed line in Fig. 5(b); see also thermal unitary-gas measurements Rem et al., 2013, Fletcher et al., 2013, Eismann et al., 2016).

Fig. 5 Universal behavior in unitary Bose gases. (a) In a weakly interacting Bose gas (left) the interactions, characterized by a , set the relevant lengthscale (size of the circles in the cartoon), so that when “zooming in” on a high-density gas it looks different to a low-density gas. In the unitary regime (right), upon zooming in, the high-density gas instead looks the same as the low-density one, exhibiting scale invariance. (b, c) Examples of experimental verification of the universality hypothesis. For initially degenerate Bose gases of initial density n_0 quenched to unitarity, both (b) the dimensionless loss rate vs. E/E_n (Eigen et al., 2017) and (c) the momentum-dependent prethermal relaxation timescale τ/t_{n_0} (Eigen et al., 2018) are universal functions that depend solely on the density. Panels adapted from: (b) Eigen, JAP Glidden, R Lopes, N Navon, Z Hadzibabic, and RP Smith (2017) Universal scaling laws in the dynamics of a homogeneous unitary Bose gas, *Physical Review Letters* 119:250404, (c) Eigen, JAP Glidden, R Lopes, EA Cornell, RP Smith, and Z Hadzibabic (2018) Universal prethermal dynamics of Bose gases quenched to unitarity, *Nature* 563:221.

¹For i -body loss, dimensional analysis gives $\dot{n}/n \propto \hbar / ma^{3i-5} n^{i-1}$ (Thøgersen et al., 2008; Mehta et al., 2009), which for $na^3 \gg 1$ gives $\dot{n}/n \propto 1/t_n$ for all i . Also note that in Bose gases Efimov physics further modulates the atom loss (Efimov, 1970; Braaten and Hammer, 2007; Naidon and Endo, 2017).

Intriguingly, the observed post-quench prethermal state featured: (1) a momentum-dependent relaxation timescale approximately given by $\hbar/\varepsilon(k)$ (see Eq. (6)) with gn replaced by E_n (see Fig. 5(c)), and (2) a universal momentum distribution, which implies a non-zero condensed fraction. This hints at the possibility of a novel superfluid state consisting of Efimov trimers,² which has also been theoretically predicted (Piatecki and Krauth, 2014; Musolino et al., 2022).

Attractive contact interactions and dipolar interactions

So far, we have only discussed the effect of repulsive contact interactions on a single component Bose gas, which for $na^3 \ll 1$ leads to relatively modest changes (see “Weak repulsive contact interactions”).

We now turn to scenarios where the interactions are (at least partially) attractive. This can lead to far more dramatic consequences and also to situations where BMF effects play a critical role. In the following, we in turn discuss: single component condensates with weak attractive contact interactions, quantum mixtures, and situations in which the atoms interact via both contact and dipolar interactions.

Attractive contact interactions

For attractive contact interactions ($a < 0$) in the thermodynamic limit, Bose–Einstein condensates are not stable, and are susceptible to collapse. This can be seen by examining the Bogoliubov excitation spectrum (Eq. (6)) and noting that negative values of g lead to imaginary excitation energies at low k , signifying unstable (exponentially growing) modes; this is sometimes referred to as a phonon instability.

Trapped (finite-sized) 3D condensates can be stabilized by the ground-state kinetic energy (quantum pressure), such that for a given atom number N , collapse only occurs above a critical attractive $|a_c|$. Note that in lower-dimensional systems the situation is somewhat different, e.g., in 1D the balance of kinetic and interaction energy permits the formation of solitons (Strecker et al., 2002; Khaykovich et al., 2002).

Condensate collapse was originally explored for atoms confined in harmonic traps (Gerton et al., 2000; Roberts et al., 2001; Donley et al., 2001) and later also for those in 3D box potentials (Eigen et al., 2016). In Fig. 6(a, b) we show, respectively, experimental images of the collapse in harmonically and box-trapped gases. In both cases, the critical point is given by $Na_c \propto L$, where L is the linear size of the single-particle ground state (see Gerton et al., 2000, Roberts et al., 2001, Donley et al., 2001, Eigen et al., 2016 and Fig. 6(c)). The basic picture can again be understood from Eq. (6): Equating $2gn$ to $\hbar^2 k^2/(2m)$ with (the minimum) $k \sim \pi/L$ (using $n \approx N/L^3$) predicts a critical value of $Na_c/L \approx -0.2$ (cf. Fig. 6(c)). More quantitatively, the collapse of such matter waves can be well described using the Gross–Pitaevskii equation.

In single-component condensates with attractive contact interactions, the BMF effects are typically negligible as a is close to zero. However, in situations where two (potentially) large MF effects cancel, BMF effects can become important and even lead to qualitatively new effects; examples of such scenarios are explored in the two following sections.

Fig. 6 Condensate collapse. (a, b) Absorption images of ultracold quantum gases following wave collapse for (a) a harmonically trapped (Donley et al., 2001) and (b) a box-trapped (Eigen et al., 2016) cloud. (c) Measured critical a_c (in units of the Bohr radius a_0) vs. $1/N$ for collapse of a condensate confined in a cylindrical box trap of size L (length equal to diameter) (Eigen et al. (2016)). The solid line shows a fit to the data, which gives $-a_c = 0.16(4)L/N$ consistent with the Gross–Pitaevskii equation prediction $-a_c = 0.17L/N$. Panels adapted from: (a) Donley, NR Claussen, SL Cornish, JL Roberts, EA Cornell, and CE Wieman (2001) Dynamics of collapsing and exploding Bose–Einstein condensates, *Nature* 412:295, (b, c) Eigen, AL Gaunt, A Suleymanzade, N Navon, Z Hadzibabic, and RP Smith (2016) Observation of weak collapse in a Bose–Einstein condensate, *Physical Review X* 6:041058.

²The Efimov effect is a quantum three-body effect first discussed in nuclear physics (Efimov, 1970).

Fig. 7 Realizing quantum droplets in Bose mixtures. (a) Illustrative phase diagram for $a_{11} = a_{22} > 0$ showing the miscible, immiscible, collapse, and droplet regimes. At the MF level for a homogeneous gas, the miscible region is given by $-\sqrt{a_{11}a_{22}} < a_{12} < \sqrt{a_{11}a_{22}}$ (between the dotted lines). Quantum droplets can be formed in a sliver of the phase diagram near $\delta a = a_{12} + \sqrt{a_{11}a_{22}} = 0$, where BMF effects can become important (see text). (b) Images demonstrating the existence of a droplet phase (Cabrera et al., 2018); for $\delta a = -3.2a_0$ (left) the cloud remains self-bound after release from the trap, compared to $\delta a = 1.2a_0$ (right), which shows the typical expansion of a miscible gas. Panel (b) adapted from Cabrera, L Tanzi, J Sanz, B Naylor, P Thomas, P Cheiney, and L Tarruell (2018) Quantum liquid droplets in a mixture of Bose–Einstein condensates, *Science* 359:301.

Interacting Bose mixtures

In a two-component quantum mixture with contact interactions between the constituents, there are three relevant scattering lengths: two intrastate ones (a_{11} and a_{22}), and an interstate one (a_{12}). A sketch of the zero-temperature phase diagram of such a mixture is shown in Fig. 7(a) for the case $a_{11} = a_{22} > 0$.

At the MF level, for $a_{12} > \sqrt{a_{11}a_{22}}$ the interstate repulsion causes the two components to separate (the system is immiscible), whereas for $a_{12} < -\sqrt{a_{11}a_{22}}$ the interstate attraction overwhelms the intrastate repulsion, leading to collapse. In between, the two components are miscible—forming overlapping condensates. The miscible-immiscible transition has been studied since the early days of atomic-gas condensates (see, e.g., Hall et al., 1998; Stenger et al., 1998; Papp et al., 2008).

At the collapse boundary, where the MF terms (almost) cancel, the residual mean-field interaction, $\delta a = a_{12} + \sqrt{a_{11}a_{22}}$, is small. However, in contrast to a single-component gas near the collapse boundary, the BMF effects are not necessarily negligible. The BMF effects are typically repulsive in nature and scale more strongly with density than the MF effects that drive the collapse, opening the possibility of quantum liquid droplets where (at an appropriate density) the attractive MF attraction can be balanced by BMF repulsion (Petrov, 2015). Such droplets were realized in 2018 (see Cabrera et al., 2018, Semeghini et al., 2018 and Fig. 7(b)). The “liquid” label refers to the fact that, in principle, the droplets are stabilized at a fixed density and are self bound; in practice, the high densities involved lead to (three-body) losses that limit the droplet lifetime. In the special case where $\delta a \approx 0$, a so-called “LHY fluid” is formed, which only features BMF interactions (Skov et al., 2021).

Dipolar interactions

In this section we briefly review novel effects of dipole-dipole interactions on Bose-condensed gases (see, e.g., Lahaye et al., 2009, Norcia and Ferlaino, 2021, Chomaz et al., 2023 for a more detailed treatment). Such interactions, which arise for particles with a permanent dipole moment, are long-range and anisotropic; the interaction potential for two polarized dipoles a distance $r = |\mathbf{r}|$ apart is given by

$$V_{\text{dd}} = \frac{C_{\text{dd}}}{4\pi} \frac{1 - 3 \cos^2 \theta}{r^3}, \quad (10)$$

where θ is the angle between $\mathbf{r}$ and the polarization axis, and C_{dd} the dipole coupling constant, which is given by $\mu_0 \mu^2 (d^2/\epsilon_0)$ for magnetic (electric) dipoles. The strength of dipolar interactions are also commonly captured by the dipolar length $a_{\text{dd}} = C_{\text{dd}} m / (12\pi \hbar^2)$.

For a homogeneous gas with both contact and dipole-dipole interactions, the Bogoliubov excitation spectrum (Eq. (6)) is modified such that

$$\varepsilon(\mathbf{k}) = \sqrt{\frac{\hbar^2 k^2}{2m} \left(\frac{\hbar^2 k^2}{2m} + 2gn + 2C_{\text{dd}} \left(\cos^2 \alpha - \frac{1}{3} \right) n \right)}, \quad (11)$$

where α is the angle between $\mathbf{k}$ and the polarization direction. Several consequences of dipolar interactions can directly be inferred from Eq. (11).

Even for weak dipolar interactions the excitation spectrum is anisotropic, which leads to anisotropic sound waves (Bismut et al., 2012). Moreover, for $C_{\text{dd}}/3 > g$ (or equivalently $a_{\text{dd}} > a$) unstable phonon modes exist and (at least from a MF perspective) the gas

Fig. 8 Dipolar Bose gases. (a) Absorption image revealing the effects of dipolar interactions following the collapse and subsequent explosion of a condensate (Lahaye et al., 2008). (b) Observation of dipolar quantum droplets (Kadau et al., 2016). (c) Sketch of the roton excitation spectrum seen in dipolar gases that are confined along their polarization direction. As the relative strength of dipole-dipole interactions increases the roton minimum deepens and then triggers (red line) an instability near k_{rot} . (d) Cartoon of the phase diagram of a dipolar gas in a cigar-shaped trap. Starting with a condensate, reducing a/a_{dd} triggers the roton instability resulting in an array of droplets. For a sliver of the phase diagram a supersolid state exists, in which the droplets are phase coherent (Tanzi et al., 2019; Böttcher et al., 2019; Chomaz et al., 2019). (e) Observation of a 2D supersolid (Norcia et al., 2021; Bland et al., 2022); (left) an in-situ image revealing a hexagonal density modulation and (right) a time-of-flight (ToF) image, averaged over multiple realizations, which demonstrates the global phase coherence of the system. Panels adapted from: (a) Lahaye, J Metz, B Fröhlich, T Koch, M Meister, A Griesmaier, T Pfau, H Saito, Y Kawaguchi, and M Ueda (2008) d-Wave collapse and explosion of a dipolar Bose–Einstein condensate, *Physical Review Letters* 101:080401, (b) Kadau, M Schmitt, M Wenzel, C Wink, T Maier, I Ferrier-Barbut, and T Pfau (2016) Observing the Rosensweig instability of a quantum ferrofluid, *Nature* 530:194,, (e) Bland, E Poli, C Politi, L Klaus, MA Norcia, F Ferlaino, L Santos, and RN Bisset (2022) Two-dimensional supersolid formation in dipolar condensates, *Physical Review Letters* 128:195302.

can undergo collapse, with the angular dependence of the interactions leading to spectacular collapse dynamics (see Lahaye et al., 2007 and Fig. 8(a)). As in the case of a Bose mixture, collapse occurs at a nonzero g , opening up the possibility of the collapse being arrested by BMF effects, which again can result in the formation of quantum droplets (see Kadau et al., 2016, Schmitt et al., 2016, Ferrier-Barbut et al., 2016, Chomaz et al., 2016 and Fig. 8(b)).

The presence of a trap tends to stabilize the system. A particularly interesting situation arises when a dipolar gas is tightly confined along the polarization direction, which leads to the development of an in-plane roton-like excitation spectrum (see Petter et al., 2019 and Fig. 8(c)). Note that although similar to the roton excitation spectrum originally seen in liquid ^4He (see, e.g., Donnelly et al., 1981), its microscopic origin is different, occurring as the consequence of both confinement and long-range anisotropic interactions. When the roton gap closes, an instability occurs at finite $k = k_{\text{rot}}$, such that without any stabilization mechanism a runaway density modulation would ensue. However, the collapse can yet again be halted by BMF effects, leading to the formation of a droplet array. For a narrow range of parameters close the stability boundary, these droplets remain phase coherent, signaling the existence of a supersolid state—a state with both long-range phase order (and hence superfluidity) and long-range spatial order (the density modulation) (see Tanzi et al., 2019; Böttcher et al., 2019; Chomaz et al., 2019; Norcia et al., 2021; Bland et al., 2022 and Fig. 8(d, e)).

Conclusion

In summary, we have reviewed effects of both contact and dipolar interactions on Bose-condensed gases. Many of the observed phenomena have been long predicted, if only more recently confirmed in ultracold gases, while others, such as the observation of supersolidity, were largely unexpected. Looking forward, further breakthroughs in both categories are within reach. A major longstanding task is to experimentally resolve the simple question of how weak interactions shift the BEC transition temperature. On the more exploratory side, the realms of strong contact and dipolar interactions offer the possibility of novel many-body physics.

Abstract

Ultracold-atom systems are an ideal quantum simulator or emulator of condensed matter physics, providing a unique approach to study strongly correlated quantum many body physics. In particular, a system of ultracold atoms loaded into an optical lattice is well described by a Hubbard model, an important minimal model in the study of condensed matter physics. High controllability of system parameters is a key to this new approach. In this chapter, we describe in detail the basic techniques as well as the recent developments of this rapidly growing field.

Key points

- Ultracold atom systems, especially those loaded into an optical lattice are an ideal quantum emulation platform of condensed matter physics, enabling the exploration of quantum many-body problems.
- Quantum emulation of a Fermi-Hubbard model as well as its SU(N) extension made possible by the use of two-electron atom system is important since classical computer cannot efficiently solve these models.
- Open quantum system can be studied with cold-atom quantum emulators by introducing the dissipation in a well-controlled manner.
- Quantum emulator of ultracold atom systems can be utilized to study topological phenomena, Thouless pump being a representative example.
- Quantum transport phenomena are studied by exploiting the state-of-the-art technologies of cold-atom systems.
- The flexibility of optical lattice setups for cold atoms enables the study of novel phenomena originating from unique band dispersions.

Introduction

Recently, atomic physicists can prepare ultracold atoms in a trap formed by a laser beam or a magnetic field in a high vacuum condition. Cooling to quantum degenerate regimes like a Bose-Einstein condensates or Fermi degenerate gases at a temperature of nano kelvin is achieved by laser cooling and evaporative cooling techniques (Ketterle and Druten, 1996). They are a closed quantum system, well isolated from the environment. Ultracold atom systems are regarded as an ideal quantum emulator or simulator of

quantum many body systems owing to the high controllability of system parameters (Bloch et al., 2008). In particular, among many, an inter-atomic interaction can be finely and widely controlled by a Feshbach resonance technique, which is not available by condensed matter systems. This leads to the realization of the Bardeen-Cooper-Schrieffer to Bose-Einstein condensate (BCS-BEC) crossover, for example. Other illustrative examples of quantum emulation studies using ultracold atoms include the physics of universal few body bound states like Efimov trimers (Naidon and Endo, 2017).

Of particular importance and interest in the study of quantum emulation of condensed matter systems is a system of ultracold atoms loaded into a periodic potential with lattice constant of the order of the laser wavelength, called an optical lattice (Bloch et al., 2008, 2012; Gross and Bloch, 2017; Schäfer et al., 2020). It is well described by a Hubbard model, which is crucially important in condensed matter physics, and is regarded as an important minimal model in the study of strongly-correlated quantum many body systems like high-temperature cuprate superconductors (Lee et al., 2006). Although only the nearest neighbor hopping t and on-site interaction U are involved, the Hubbard model captures the essence and provides the explanation of diverse phenomena observed in condensed-matter physics. Quantitative understandings that can be obtained from the quantum emulation of strongly correlated many-body systems will offer unique guidelines for synthesis of novel materials.

Key issues

Here, we note that it is obvious that experiments using ultracold atoms are not always regarded as quantum emulation. Then, in what conditions should the experiments performed using cold atoms be termed as quantum emulation? Here, we provide a brief comment on the requisite for quantum emulation using ultracold atoms (Qiu et al., 2020). We think that, at least, the Hamiltonian or model of the target system should be clearly defined with reasonable grounds, and only the difficulty to describe an observed behavior by a mean-field theory, or the complexity to calculate static or dynamic properties of the system, for example, should be insufficient. One illustrative example of quantum emulation research from the engineering point of view is the computationally hard problem of Fermi-Hubbard model (FHM) where the sign-problem prevents the efficient numerical approach with quantum Monte-Carlo methods. From the viewpoints of scientific importance, on the other hand, one can target the conceptually important phenomena like topological quantum phenomena, no matter how computationally hard or not.

One of the important advantages of quantum emulation approach of condensed matter physics using ultracold atoms is rich varieties of interesting research topics. Fig. 1 illustrates some examples of interesting optical lattice quantum emulation research topics. These include non-equilibrium dynamics, potential disorder, $SU(N)$ spin symmetry, non-standard lattice, topological physics, open quantum dynamics, quantum mixtures, quantum transport, synthetic gauge field, and so on.

Overview

In this article, we describe in detail the basic techniques as well as several interesting research topics of optical lattice quantum emulation research. In Section “Optical lattice minimum,” the basic knowledges and techniques required to understand the optical lattice system are summarized. In particular, we pay special attention to a powerful technique of quantum gas microscopy. The following sections are devoted to the focused discussion on the selected topics. In Section “Ultracold Fermions as Fermi-Hubbard-Model emulation,” we describe in detail a system of ultracold fermions as Fermi-Hubbard-model emulator, with the special emphasis on the unique possibility of studying $SU(N)$ Fermi-Hubbard model. Section “Cold atom realization of dissipative Hubbard model as open quantum system emulation” describes the cold-atom realization of dissipative Hubbard model as an open quantum system emulator, which is of recent interest. In Section “Cold atom realization of Thouless pump as topological physics emulation,” we describe the cold-atom realization of Thouless pump as an illustrative example from the viewpoint of the

Fig. 1 Few examples of interesting optical lattice quantum emulation research topics.

emulation of topological physics which is intensively and extensively studied in condensed matter physics. Section “Two-orbital cold atom system as quantum transport emulation” is devoted to the discussion on the quantum transport emulation of the Kondo effect as well as mesoscopic quantum transport. The final focused topic described in Section “Non-standard optical lattice system as novel energy-band emulation” is a non-standard optical-lattice system as novel-energy-band emulation, with special emphasis on a Lieb lattice. We conclude this article by describing the summary and future directions in the final Section “Conclusion.”

Optical lattice minimum

Fig. 2 shows the schematic view of an optical lattice. A variety of atomic species have been successfully cooled to quantum-degenerate regimes, such as rather standard alkali-metal, alkali-earth-like, and magnetic lanthanide atoms (Schäfer et al., 2020). These ultracold atoms are first prepared in a weak harmonic trap. Then, adiabatic ramping-up of an optical lattice potential results in a successful loading of the ultracold atoms into an optical lattice with no significant heating effect. Sufficiently deep optical lattice potential enables us to treat the atoms in an optical lattice by the tight-binding model where an atom is localized on each lattice site and undergoes hopping between adjacent lattice sites. A single-band Hubbard model, then, describes the behavior of the atoms by a tunneling term characterized by a tunneling energy t and an on-site interaction term characterized by an energy U when more than two particles occupy the same lattice site. In addition, a weak external confinement is superimposed to a periodic optical lattice potential and is described as a site-dependent energy offset ϵ_i where i represents the site index. Multiple occupancy sites are created, depending on the total number of atoms and the external confinement.

Controllability of parameters

As is mentioned, the Hubbard model is characterized by important parameters of a tunneling energy t and an on-site interaction energy U . Different from the ordinary condensed matter system, the ratio of these two parameters is precisely controlled experimentally by tuning the depth of the optical lattice potential. Individual control of these two is also possible. Feshbach resonances (Chin et al., 2010) provide the novel possibility of controlling the strength as well as sign of the on-site interaction, while the strength, sign, and even the complex phases (Peierls phases) of the tunneling energy t can also be controlled by lattice shaking and Raman-assisted tunneling methods. As in the condensed matter system, filling factor, temperature, and the total atom number can be finely controlled.

Measurement methods

Here, we review some basic measurement methods. The time-of-flight (TOF) method, in which the optical lattice potential is suddenly turned off and the atom imaging is taken after a certain time, TOF, provides the information of atomic coherence over the lattice sites, which is the key for the observation of the superfluid-to-Mott insulator transition of the Bose-Hubbard model, where the sharp interference peaks of TOF images is an important signature of superfluid phase and the vanishing of the interference Mott-insulator (Greiner et al., 2002). In the slight modification of TOF method, known as band-mapping method, TOF images are taken after adiabatic ramp-down of the optical lattice, enabling the measurement of quasi-momentum distributions of the atoms (Bloch et al., 2008). In addition, the application of a spin-dependent potential gradient just before TOF measurement enables the spin-resolving imaging through a Stern-Gerlach effect.

High-resolution spectroscopy using radio-frequency and optical clock transition resolves the spectra from different occupancies (Schäfer et al., 2020). Spin correlation is the observable of great interest in the study of quantum magnetism. Similar to the solid-state quantum dot systems, a singlet-triplet-oscillation protocol is developed for cold atom systems to reveal the spin correlation between nearest-neighbor sites by combining the methods of superlattice, photo-association, Feshbach resonance, or a band mapping (Trotzky et al., 2010; Greif et al., 2013; Ozawa et al., 2018). Long-range coherences of a superfluid phase of bosons are successfully detected by exploiting the Talbot effect incorporating the in-trap atom expansion (Santra et al., 2017). Berry curvature

Fig. 2 Schematic view of an optical lattice.

and topological invariants are successfully measured through the excitation rate measurement to higher bands after amplitude modulation, revealing a quantum geometric tensor or through a shift of an atom cloud in the case of Thouless pump, for example.

Quantum gas microscopy

Ultimately, the atom distribution in a 2D optical lattice is measured by single-site resolving imaging of quantum gas microscopy (QGM), enabling the study of a quantum many-body system in a direct manner (Gross and Bloch, 2017). The QGM method is first developed for a bosonic atom of ^{87}Rb by utilizing the favorable features of cooling and imaging. The quantum phase transition of superfluid to Mott insulator states has been successfully demonstrated from the spatial distribution of atoms. In particular, the density plateau is directly confirmed as well as the particle-hole correlations in the Mott insulating state. The ability to observe the single-site resolving imaging is also utilized to a single-atom addressing technique, enabling the studies of non-equilibrium dynamics like a quantum walks, spin wave propagations, quantum thermalization, and quantum many-body localization. From the quantum information research perspective, entanglement entropy is directly measured. The QGM is also applied to fermionic atoms by developing efficient cooling methods, which is described in the next section.

Ultracold Fermions as Fermi-Hubbard-Model emulation

In the context of condensed matter physics emulation, ultracold fermions in an optical lattice play a fundamental role, as strongly correlated many-body systems of fermionic particles of electrons do in condensed-matter physics (Auerbach, 2012). A new approach made possible by using ultracold fermionic atoms in optical lattices will give important insights for strongly correlated electron systems. Here, we describe in more detail the recent experiments using ultracold fermions as Fermi-Hubbard-Model emulation.

As is mentioned, a system of ultracold fermions in an optical lattice is well described by the Fermi-Hubbard model (FHM),

$$H^{\text{FHM}} = -t \sum_{\langle i,j \rangle, \sigma} c_{i,\sigma}^\dagger c_{j,\sigma} + U \sum_i n_{i,\uparrow} n_{i,\downarrow} + \varepsilon_i \sum_{i,\sigma} n_{i,\sigma} \quad (1)$$

where $c_{i,\sigma}$ is fermionic annihilation operator for site i and spin $\sigma = +1/2(\uparrow)$ or $-1/2(\downarrow)$, $n_{i,\sigma} = c_{i,\sigma}^\dagger c_{i,\sigma}$ is the number operator, and ε_i represents the weak potential offset superimposed to the optical lattice potential.

In this case of two-component or SU(2) FHM, similar to the electrons, as a higher temperature phase, a paramagnetic Mott insulator state emerges when the interaction is strongly repulsive. However, at a lower temperature below the Néel temperature, quantum magnetism manifests itself as an antiferromagnetic ordered state, as a result of the super-exchange interaction (Moriya and Ueda, 2003). Quantum emulation of the Fermi Hubbard model is especially important since the understanding of the behaviors of doped 2D SU(2) FHM at low temperatures, key for high-Tc superconductivity, still escapes complete understanding in spite of intensive studies in both condensed matter theory and experiments (Lee et al., 2006).

Mott insulating phases of cold atom FHM have been realized and studied by various techniques. In particular, the QGM is quite useful for studying the cold atom FHM, and especially QGM with a spin resolving ability is a powerful method for the short- as well as long-range spin correlation measurements of FHM. In fact, the QGM method enables the observation of an antiferromagnetic correlation and ordered phase (Mazurenko et al., 2017). More recent studies explore the doped region of Fermi-Hubbard model, revealing the non-local correlations of string orders. Toward the goal of realization of the d -wave superfluidity of FHM, further cooling of fermions in optical lattices is crucially important. Local manipulation of the optical lattice potential using elaborate spatial light modulating devices enables the successful demonstration of powerful strategy of entropy redistribution, leading to the temperature of $0.25(2)/k_B \times t$ (Mazurenko et al., 2017). Here k_B is the Boltzmann constant.

Cold atom SU(N) fermion system

Beyond the scope of the emulation of traditional condensed matter systems, a new state of matter can be realized by utilizing novel possibilities available in ultracold atomic systems. As one illustrative example, we can here describe in detail the realization of SU(N) Fermi Hubbard model. Originally, the study of SU(N) Hubbard model has started from a purely theoretical interest as an extension of the conventional SU(2) Fermi Hubbard model (Affleck, 1985), and now reveals rich quantum phases (Wu et al., 2003; Cazalilla and Rey, 2014). The enhancement of quantum fluctuation causes qualitatively different behaviors from those of SU(2) model. The SU(N) FHM is described by the following Hamiltonian Eq. (2)

$$H^{\text{SU(N)FHM}} = -t \sum_{\langle i,j \rangle, \sigma} c_{i,\sigma}^\dagger c_{j,\sigma} + U \sum_{i, \sigma \neq \sigma'} n_{i,\sigma} n_{i,\sigma'} + \varepsilon_i \sum_{i,\sigma} n_{i,\sigma} \quad (2)$$

where $\sigma = 1, 2, \dots, N$. Note that the hopping matrix element t and on-site interaction U do not depend on the spin σ , which assures the SU(N) symmetry.

Implementation of SU(N) Fermi Hubbard model is realized by using fermionic isotopes of alkali-earth-like atoms, such as ytterbium (^{173}Yb) and strontium (^{87}Sr). In these atoms, the electron and nuclear spin angular momenta are decoupled in the ground 1S_0 and metastable 3P_0 states. This results in the independence of the inter-atomic interaction with respect to the spin degrees of freedom σ , here corresponding to the nuclear spin I , which is key for realizing the $\text{SU}(N = 2I + 1)$ FHM.

A high temperature phase of a paramagnetic SU(N) Mott insulator is realized by loading the SU(N) fermions into an optical lattice. This is confirmed by several signatures like the charge excitation gap, suppressed compressibility $\partial n/\partial \mu$, low temperature estimated by doublon-production-rate measurement (Taie et al., 2012) and in situ observation of a Mott plateau (Hofrichter et al., 2016).

Quantum magnetism or spin correlation expected at a lower temperature phase is studied for various lattice geometries including 1D, 2D, 3D, and a dimerized lattice. An STO technique, first developed for quantum-dot system and later applied to cold atom system of bosons (Trotzky et al., 2010) and fermions (Greif et al., 2013), is successfully applied to observe the nearest-neighbor antiferromagnetic spin correlations of SU(N) fermions of ^{173}Yb (Ozawa et al., 2018). In particular, the experimental data for a system of SU(6) fermions in a 1D lattice is compared with the theoretical calculations based on exact diagonalization and determinantal quantum Monte-Carlo methods, indicating the achieved temperature of about 0.1 of the tunneling energy t (Taie et al., 2022). This corresponds to the lowest temperature ever achieved for ultracold fermions. The observed significant cooling effect for the SU(6) system is attributed to the enhanced Pomeranchuk cooling effect, first observed in solid ^3He . Note that even the state-of-the-art theoretical calculations are not powerful to quantitatively explain the data for higher dimensions, illustrating the importance of the SU(N) fermion system as quantum emulator.

Cold atom realization of dissipative Hubbard model as open quantum system emulation

Open quantum system

One of the recent considerable interests in condensed matter physics, especially in theory, is the study of open quantum systems. This is reasonable because the dissipation is ubiquitous in real condensed matter systems. Theoretically, an introduction of coupling between a closed quantum system with the environment calls the necessity to describe the system dynamics by Liouvillian dynamics, which is qualitatively different from a unitary dynamics of an isolated, closed quantum mechanical system. The novel role of the dissipation as a tool for preparation of certain quantum states is recently discussed (Daley, 2014; Müller et al., 2012).

As an example, here we consider the case of a dissipative Bose-Hubbard model with two-body dissipation. The master equation for density operator ρ describing this system is given as,

$$\hbar \frac{d}{dt} \rho = -i[H^{\text{BHM}}, \rho] + L_2(\rho), \quad (3)$$

$$H^{\text{BHM}} = -t \sum_{\langle i,j \rangle} b_i^\dagger b_j + U \sum_i n_i(n_i - 1)/2, \quad (4)$$

$$L_2(\rho) = \frac{\hbar\Gamma}{4} \sum_i \left(-b_i^\dagger b_i^\dagger b_j b_j \rho - \rho b_i^\dagger b_i^\dagger b_j b_j + 2b_j b_j \rho b_i^\dagger b_i^\dagger \right), \quad (5)$$

where b_j represents boson annihilation operator and Γ denotes the strength of the two-body dissipation.

Dissipation in cold atom experiment

Ultracold atoms in an optical lattice is in itself a well-defined closed quantum many-body system, isolated in a vacuum chamber. Therefore, when one artificially introduces dissipation processes in a well-controlled manner, one has a novel possibility of realizing open quantum system with engineered dissipation. In fact, various types of dissipation, such as a one-body dissipation via an electron beam (Labouvie et al., 2015) and well-controlled photon scattering process (Patil et al., 2015; Takasu et al., 2020), two-body loss via a molecular inelastic collision (Syassen et al., 2008; Yan et al., 2013) and photo-association (Tomita et al., 2017), and three-body loss via a Feshbach resonance (Mark et al., 2012) are successfully introduced to a cold atom system. The successful implementation of dissipation process reveals the novel behaviors due to the dissipation, such as the localization of particle, quantum Zeno effect, stabilization of the Mott insulator, realization of PT-symmetric state, formation of ferromagnetic spin correlation indicating the negative spin temperature (Honda et al., 2023), and so on.

Cold atom realization of Thouless pump as topological physics emulation

Another example of the research topics of considerable interests in condensed matter physics is topological physics. Especially in recently years, there has been impressive progress in topological solid-state material synthesis. The theoretical backgrounds of these recent studies can be found in the seminal paper (Thouless et al., 1982) by Thouless, Kohmoto, Nightigale, and den Nijs (TKNN) in which the quantization of the Hall conductance for the integer quantum Hall effect is revealed as a topological invariant known as a

Chern number. High controllability of ultracold atoms in optical lattices enables the researchers to realize various topologically-non-trivial systems (Goldman et al., 2016).

In another seminal 1983's Thouless paper (Thouless, 1983), the quantization of the charge transferred in each pumping cycle for a periodically driven electron gas in an infinite one-dimensional periodic potential is revealed as a topological invariant. Importantly, these seemingly different phenomena share the same topological origin. Topological robustness inherent in these phenomena are also crucially important from the viewpoints of the application to the standard: the quantized Hall conductance and Thouless pump can serve as very accurate standards for electric resistance and electric current, respectively.

Thouless pump in cold atom experiments

Successful demonstration of the Thouless charge pump (Nakajima et al., 2016; Lohse et al., 2016) is achieved by constructing a controllable one-dimensional periodic potential consisting of an optical superlattice and loading ultracold bosonic or fermionic atoms. These experiments are based on the specific lattice model of a Rice-Mele model given in Eq. (6),

$$H^{\text{RM}} = \sum_i \left(-(J + \delta)a_i^\dagger b_i - (J - \delta)a_i^\dagger b_{i+1} + \text{h.c.} + \Delta(a_i^\dagger a_i - b_i^\dagger b_i) \right), \quad (6)$$

where a_i and b_i are annihilation operators of an atom in the two sublattices of the i -th unit cell, $J \pm \delta$ is the tunneling amplitude within and between unit cells, and Δ denotes a staggered on-site energy offset. Temporal periodic change of the dimerized hopping amplitude δ and staggered energy Δ , forming a particular trajectory in the δ - Δ parameter space, drives Thouless pumping, the topology of which is determined by the trajectory that encircles the degeneracy point of $\delta = \Delta = 0$. The quantization of Thouless pumping manifests itself as the quantized shift of the atomic cloud. In particular, the experiments with various pumping sequences reveal the topological natures of this pumping: relevance on the winding number of the trajectory around the degeneracy point as well as the irrelevance on the details of the trajectory.

Two-orbital cold atom system as quantum transport emulation

From the viewpoints of quantum emulation of condensed matter physics, two-electron atoms, or alkali-earth-like atoms are unique in that their long-lived metastable states like the 3P_0 and 3P_2 electronic states, combined with the ground state 1S_0 enables the study of the multi-orbital physics. These metastable states are accessible from the 1S_0 state through a coherent excitation utilizing very stable lasers with a Hz-level linewidth, which also attracts much attention for the application to an optical frequency standard. In addition to the inter-orbital spin-exchange interaction for nuclear spin degrees of freedom, the existence of a magnetic (orbital) Feshbach resonance between the ground 1S_0 and 3P_2 (3P_0) states offers the powerful control of the interatomic interaction between the atoms in these states.

Among the spin-orbital-related physics so far studied in condensed matter physics, the Kondo effect (Kondo, 1964), arising from an antiferromagnetic spin-exchange interaction between conduction electrons and magnetic impurities, is quite important, since it is one of the central problems of the strongly-correlated quantum many-body physics. In the case of periodically aligned localized spins, the corresponding system is described by the Kondo lattice model, exhibiting rich quantum phases like a paramagnetic phase and the Ruderman-Kittel-Kasuya-Yoshida ordered phase in a Doniach phase diagram (Doniach, 1977). The system is described by the following Hamiltonian H^{KLM} ,

$$H^{\text{KLM}} = -t_c \sum_{\langle i,j \rangle, \sigma} c_{i,c,\sigma}^\dagger c_{j,c,\sigma} + V^{\text{ex}} \sum_{i, \sigma \neq \sigma'} c_{i,c,\sigma}^\dagger c_{i,l,\sigma'}^\dagger c_{i,c,\sigma'} c_{i,l,\sigma}, \quad (7)$$

where t_c is the tunneling amplitude in the conduction band, V^{ex} the spin-exchange energy between the conduction electron and localized impurity, and the symbols c and l the conduction and localized orbitals, respectively. We note that, for a system of alkali atoms, there are also several proposals of cold atom quantum emulator of the Kondo effect.

Two-orbital two-electron atom system as Kondo-effect emulation

Owing to the existence of two-orbital as well as spin degrees of freedom, as is mentioned, it is quite natural to consider a system of two-electron atoms as an experimental platform of Kondo-effect or Kondo lattice model emulator (Gorshkov et al., 2010). We can expect that the application of a quantum gas microscope technique for two-electron atoms will reveal the Kondo screening behavior, for example. However, this does not mean that any two-electron atoms can be used for this emulation. In order to study the Kondo effect, the interorbital spin-exchange interaction should be antiferromagnetic, which makes only a fermionic isotope of ^{171}Yb a natural candidate (Ono et al., 2019), while an interesting possibility of controllability of spin-exchange interaction is theoretically proposed and experimentally demonstrated for ^{173}Yb atoms with a ferromagnetic spin-exchange interaction. Toward this goal, progresses are obtained like a construction of localization-itinerant mixed-dimensional two-orbital optical lattice system and a successful observation of the spin-exchange dynamics between ^{171}Yb atoms in the 1S_0 and 3P_0 states (Ono et al., 2021a).

Cold atom system as mesoscopic quantum transport emulation

In solid state mesoscopic materials, there have been extensive studies on quantum transport of electrons between terminals through narrow channels (Ihn, 2010; Imry, 2002). The quantized conductance, predicted by the Landauer formula, is one illustrative example.

High controllability and state-of-the-art optical trapping technique enable the realization of narrow conduction channels for quantum transport experiments using ultracold atoms (Krinner et al., 2017). This quantum emulator using ultracold atoms, extended to mesoscopic quantum transport research, is called atomtronics. A series of elaborate experiments have established a cold-atom analog of mesoscopic quantum point contact, verifying conductance quantization, for example (Krinner et al., 2015). More recently, a novel scheme of a quantum transport emulation using the spin degrees of freedom is proposed (You et al., 2019, and Nakada et al., 2020), and experimentally realized (Ono et al., 2021b). In particular, the use of a multicomponent spin system enables the realization of a multiterminal quantum point contact system.

Non-standard optical lattice system as novel energy-band emulation

Recent advance of highly sophisticated laser technologies makes not only standard but also various types of optical lattice geometries available for quantum emulation experiments. In fact, various geometries of optical lattices are realized (Windpassinger and Sengstock, 2013). In addition to standard 1D, 2D, or 3D lattices, non-standard lattices of superlattices (Fölling et al., 2007), triangular lattices (Becker et al., 2010), Kagomé lattices (Jo et al., 2012), Lieb lattices (Taie et al., 2015), honeycomb lattices (Tarruell et al., 2012), quasi-crystal potentials (Viebahn et al., 2019) are successfully formed, for example, enabling the study of geometric frustration, topology, and so on.

Novel geometries of lattice structures lead to interesting energy bands which will play crucial roles in the manifestation of the novel quantum phases. For example, a honeycomb lattice shows a linear dispersion of Dirac cone, and the Kagomé lattice structure exhibits a totally vanishing dispersion, called a flat band with the macroscopic degeneracy.

Optical Lieb lattice system as novel flat-band emulator

Here, we describe in detail a Lieb lattice as an illustrative example of optical-lattice realization of interesting non-standard lattice structure. Cold-atom systems provide the possibility to study exotic phases like supersolids using bosons loaded into a Lieb lattice as a result of interplay between frustrated kinetic energy and inter-atomic interactions, as well as the ferromagnetism using fermions based on the Lieb's theorem.

The Lieb lattice supports the flat band as well as the Dirac cone, and is also called a d - p model since it is identical to the lattice structure of the CuO_2 plane of high- T_c superconductors. The lattice structure of the Lieb lattice involves three sublattices A, B, and C, in which A-sites forms a square lattice and B- and C-sites are located on every line of the square lattice. Taking only the nearest-neighbor tunneling t into consideration and considering the quasi-momentum eigenstates $|q, A\rangle$, $|q, B\rangle$, and $|q, C\rangle$ as basis sets, the tight-binding Hamiltonian can be described by transfer matrix M , given by

$$M = \begin{pmatrix} 0 & -2t\cos(q_x d/2) & -2t\cos(q_y d/2) \\ -2t\cos(q_x d/2) & 0 & 0 \\ -2t\cos(q_y d/2) & 0 & 0 \end{pmatrix}, \quad (8)$$

where d denote the lattice constant. The diagonalization of this transfer matrix gives the energy-bands and the eigenvalues. Importantly, the second energy-band of the Lieb lattice exhibits the flat band with no energy dispersion, with the eigenstates given by a superposition of only the B- and C- sites,

$$|q, \text{FB}\rangle = \cos \theta_q |q, B\rangle - \sin \theta_q |q, C\rangle \quad (9)$$

where $\tan \theta_q = \cos(q_x d/2)/\cos(q_y d/2)$. Note that the flat band structure is not originated from a zero hopping energy but from the destructive interference between the hopping from B- to A- sites and that from C- to A- sites.

Optical-lattice realization of the Lieb lattice is done by superimposing three different kinds of optical lattices by exploiting the high flexibility of laser phases and wavelengths. The controllability of the optical lattice parameters enables the direct observation of the localization of a matter wave within the B- and C- sites in the flat band, different from the delocalization in a usual dispersive band. In addition, the structure of the transfer matrix M suggests the analogy between the phenomenon of Stimulated Raman Adiabatic Passage (STIRAP) process (Bergmann et al., 1998), studied both theoretically and experimentally in quantum optics, and the Lieb lattice, studied in condensed matter physics. In fact, this is the nice example in which the phenomena discussed in different fields of physics can be understood on the same grounds. This close analogy provides the interesting manner of understanding of the flat band. Namely, the eigenstate of the flat band is nothing but a dark state which does not couple with electromagnetic fields applied in the STIRAP process.

This analogy between the Lieb lattice and laser-coupled three-level system considered in a STIRAP process not only provides the deeper understanding but also the novel possibility of realization of a matter-wave analog of the STIRAP, called spatial adiabatic passage, or transport without transit (Rab et al., 2008). According to this analogy, we can consider novel quantum transport of a quantum-mechanical particle between well-separated positions of B- and C- sites in real space, with no possibility of finding the atoms at the intermediate position of A-site. In fact, this novel transport is realized experimentally (Taie et al., 2020).

Conclusion

In summary, after the basic techniques of an optical lattice are introduced, we described several interesting research topics of quantum emulation of condensed matter physics. The discussed topics include quantum emulation of Fermi-Hubbard-model, dissipative Hubbard model, Thouless pump, quantum transport, and a Lieb lattice model.

Here, we briefly mention other important topics which are not involved in the former sections. The first is the study of the nonequilibrium dynamics of a quantum many-body system. It is noted that an optical lattice quantum emulator is ideal for this purpose, owing to the high controllability, especially for the lattice potential and interatomic interaction in a time-dependent manner, allowing for the study of Kibble-Zurek mechanism across phase transitions (Braun et al., 2015) and the dynamical spreading of quantum information and the Lieb-Robinson bound (Cheneau et al., 2012). This is particularly important since the long-term dynamics of quantum many-body system after quantum quench is in general quite hard to simulate with classical computers, and thus the experimental results can serve as a versatile benchmark for developing a new numerical technique.

In addition to the regular periodic lattice potentials, introducing disorder potentials enables the quantum emulation of disorder-induced phenomenon such as Anderson localization (Billy et al., 2008; Roati et al., 2008), many-body localization (Abanin et al., 2019), and so on. Disordered potentials are introduced by a number of ways like imprinting speckle patterns, superpositions of optical lattices at incommensurable lattice spacings, and introducing atomic impurities.

In spite of the fact that ultracold atoms are neutral in charge, recent developments of cold-atom quantum emulation technologies successfully introduce artificial gauge fields, spin-orbit coupling and topologically non-trivial bands in optical lattices (Cooper et al., 2019). The notion of synthetic dimensions (Ozawa and Price, 2019) is also actively applied to the study of quantum emulation of condensed matter physics. A rich variety of parameter spaces spanned by time, internal degrees of freedom of atoms, and well-defined atomic momentum are available in a cold-atom system. Note that already explained example of Thouless pump utilizes the time as one of the two dimensions required for defining the Chern number. Furthermore, Raman-coupling of internal states can implement spin-orbit coupling in cold atom systems, enabling the various research related with condensed matter physics.

Here, we also briefly note on the recent development of the novel optical trapping system, called an atom tweezer array system (Saffman et al., 2010; Kaufman and Ni, 2021), which offers rather complementary possibilities with the optical lattice platform. By tightly focusing laser beams created by spatial light modulating devices with a high-numerical aperture objective lens, single atoms are trapped in defect-free atomic arrays with spacings of about a few micrometer with rather arbitrary geometries in one, two, and three dimensions. Moreover, Rydberg state excitation can induce strong interaction between the atoms in neighboring sites of a tweezer array. The Rydberg atom tweezer array system is now extensively used for quantum emulation of Ising spin model and reveals quantum thermalization problem like a quantum many-body scar, for example.

The final remark is on an interesting future possibility of performing remote quantum emulation experiment (Heck et al., 2018) by anyone, including condensed matter theorists, who is not an expert of cold-atom experiments that require the knowledge and experience to operate very complicated machines. Such a remote quantum emulation system will enhance the development of new numerical calculations.

Acknowledgments

We greatly thank many experimental and theoretical collaborators to understand the works described in this article. Especially, we thank Y. Takasu, S. Taie, S. Nakajima, H. Ozawa, R. Yamamoto, Y. Takata, N. Kitamura, K. Honda, Y. Nakamura, T. Kusano, K. Ono, T. Ishiyama, and T. Takano, for experiment, and I. Danshita, S. Goto, M. Yamashita, K. Inaba, Y. Kuno, S. Uchino, Y. Nishida, L. Wang, K. Hazzard, R. T. Scalettar, and E. Ibarra-García-Padilla for theory. The work was partially supported by the Grant-in-Aid for Scientific Research of JSPS (Nos. JP17H06138, JP18H05405, and JP18H05228), the Impulsing Paradigm Change through Disruptive Technologies (ImPACT) program, JST CREST (No. JP-MJCR1673), MEXT Quantum Leap Flagship Program (MEXT Q-LEAP) Grant No. JPMXS0118069021, and JST Moonshot R&D – MILLENNIA Program (Grant No. JPMJMS2269).

Abstract

Ion transport plays a key role in solid state science. It is not only conceptually important, it is also key to solid state devices in energy research. Moreover, the kinetics of solid state chemical processes typically rely on it. If electron transport is involved as well, redox processes can occur, e.g., storage processes in lithium or sodium batteries. Of particular significance are ionic and mixed conductivity processes in interfacially dominated and/or confined systems (Nanoionics). The latter establishes natural ties to biology. The article traces back all these phenomena to the respective mechanistic centers (e.g., point defects in ionic solids) and to the basic thermodynamic and kinetic relations.

Key points

- Basics and mechanisms of ion transport.
- Ionic charge carriers in pure, doped and partially frozen states.
- Transport in bulk, at interfaces, and in confined systems.
- Ion transport enabling electrolyte function and nerve signals.
- Mixed conductivity and ambipolar transport enabling electrode storage and compositional changes.

Introduction: Hopping process

While a quantum mechanical particle such as quasi-free-electron can tunnel through a barrier by interference of the states on both sides of the barrier (denoted by x and x'), that is, by seizing the hindrance in a wave-like way, the transport of a heavy particle such as an ion has to rely on the ensemble fraction with energy high enough to reach the final state (hopping) (Allnatt and Lidiard, 1993; Maier, 2004). On the one hand, under favorable circumstances protons may also tunnel, while on the other hand electrons that strongly polarize their environment (large polarons) behave almost classically as ions. In most cases of interest (consider A as an ion with charge z_A), the hopping of A from x to x' ($x' = x + \Delta x$) may be written as.

(The dash takes account of the possibility for A to have a different structural environment at x'). In cases where A denotes an ion on a regular site in a crystal, V is the vacancy that serves as a jump partner, while in cases where A refers to an excess ion sitting on interstitial sites, V denotes the vacant interstitial site. In crystals, V (in the first case) or A (in the second case) are usually diluted with the energy levels of these sites being well defined. The concentration of the respective reaction partner is then approximately constant and the corresponding rate equation for the hopping process is pseudo-monomolecular. In amorphous solids, the sites are

[☆]Change History: September 2022. J Maier updated sections Nano-Ionics, Chemical diffusion in mixed conductors and battery storage, Ion transport in biology, Summary and Figures 16 and 17.

less defined, which also holds for the spatial energy distribution; in polymers, melts or liquids, these sites and energy distributions fluctuate. In these cases, one would better speak of smeared-out density of states, as far as thermal excitations are concerned. The rate constant for the hopping rate equation is decisively influenced by the activation free enthalpy. The parameters k and $\Delta G^\ddagger$, for example, for the forward reaction (index $\rightarrow$) related through (prefactor k_0 is proportional to the attempt frequency Γ_0)

$$\vec{k} = k_0 \exp\left(\frac{\vec{\Delta G}^\ddagger}{RT}\right) \quad (2)$$

refer to the built-in part of the forward rate constant and its activation free energy, respectively. This expression has to be complemented by the factor $\exp\left(-\vec{\alpha}\Delta\phi F/RT\right)$ in order to take account of the applied electric field. The parameter $\Delta\phi$ is that part of the external voltage that drops from x to x' and the term $\vec{\alpha}\Delta\phi$ measures the portion of $\Delta\phi$ that is relevant for the forward reaction (distance between saddle point and initial state).

The relations for the backward reaction are analogous ($\vec{\alpha} + \bar{\alpha} = 1$). This leads to the Butler-Volmer equation which describes the charge transfer from x to x' for an asymmetric free-energy profile. In the homogeneous bulk region (and also in the space charge region sufficiently far from the interface, i.e., $A = A'$), the built-in profile is symmetrical, that is, ($\vec{k} = \bar{k} = k$, $\vec{\alpha} = \bar{\alpha} = 1/2$) and $\vec{\Delta G} = \bar{\Delta G}$. The result for the rate represented by the current density i_j of carrier j in x -direction

$$\begin{aligned} i_j &= -2k_j c_j z_j F \sinh \frac{z_j F \Delta\phi}{2RT} \\ &\simeq -\sigma_j \frac{\Delta\phi}{\Delta x} \end{aligned} \quad (3)$$

can be simplified to Ohm's law (bottom part) for $\Delta\phi \ll RT/z_j F$; the conductivity σ_j of the carrier is proportional to its mobility u_j ($u_j \propto k_j$), (molar) concentration (c_j) and (molar) charge ($z_j F$) and given as

$$\sigma_j = z_j F u_j c_j \quad (4)$$

Allowing also for a concentration variation during the process and generalizing to three dimensions, but restricting to small effects the Nernst-Planck equation is arrived at

$$i_j = -D_j z_j F \nabla c_j - \sigma_j \nabla \phi \quad (5)$$

where the diffusion coefficient (D) and conductivity (σ) are related through the Nernst-Einstein equation. Close to equilibrium, this equation corresponds to the result obtained by linear irreversible thermodynamics,

$$i_j = \frac{\sigma_j}{z_j F} \nabla \tilde{\mu}_j \quad (6)$$

which assumes the current to be proportional to the gradient in the electrochemical potential $\tilde{\mu} = \mu + zF\phi$ (chemical potential + (molar charge x electrical potential)). The latter relation is more general concerning the concentration range, while the former (as regards the diffusion term) is a little more general as far as the magnitude of this driving force is concerned. In cases where the current of a given species is also generated by secondary driving forces (e.g., by $\nabla \tilde{\mu}$ of a different particle), cross terms occur for which the Onsager-Casimir symmetry relations are valid. Also Eq. (6) can be generalized towards higher driving forces. Maier (2004) and Riess and Maier, 2008 give a symmetrized relation in terms of the electrochemical potential drop over the jump distance appearing as exponent in a sinh-function (similar as in Eq. (3)). As regards the determination of the conductivity, the first task is to determine the carrier concentration as a function of the control parameters. This is feasible by solving the defect model for the system under consideration.

Charge carrier concentrations in pure compounds and dilute bulk

Fig. 1 displays the fundamental charge carrier formation reaction in an "energy level" diagram for a fluid (H_2O) and an ionic crystal ($AgCl$) (Maier, 1993a). These levels refer to effective standard (electro) chemical potentials or—in the case of the "Fermi levels" that are positioned within the gap—full (electro) chemical potentials. (As long as the bulk is considered, $zF\phi$ can be neglected and one can refer to μ instead of $\tilde{\mu}$.) As long as—in pure materials—the gap remains large compared to RT , the Boltzmann form of the chemical potential of the respective charge carrier (defect) is valid which has the form

$$\mu_j = \mu_j^\circ + RT \ln \left(\frac{c_j}{c_j^\circ} \right) \quad (7)$$

As outlined below, this relation holds largely independent of the charge carrier situation and the form of the energy level distribution. If the levels are smeared out or if there is a band of levels, μ_j° refers to an effective level (i.e., band edges in nondegenerate semiconductors or an appropriately averaged energy when dealing with fluids or disordered solids). The coupling of the ionic level picture and the electronic level picture for $AgCl$ (Fig. 2) is established via the thermodynamic relation

Fig. 1 Electronic and ionic disorder in ionic solids and water in “physical” (top) and “chemical” language (bottom).

Fig. 2 Coupling of ionic and electronic levels in AgCl .

$\tilde{\mu}_{\text{Ag}^+} + \tilde{\mu}_{\text{e}^-} = \mu_{\text{Ag}}$ and hence via the component potential which reflects the precise position in the phase diagram. The meaning of μ^0 becomes obvious, if for simplicity one considers an elemental crystal (with defect j). For the formation of N_j identical defects (among N regular positions), a local free enthalpy of $N_j \Delta g_j^0$ is required in the interaction-free case; including also the configurational contribution, the Gibbs energy of the defective crystal (G_p refers to the perfect crystal) reads

$$G = G_p + N_j \Delta g_j^0 - k_B T \ln \left(\frac{N}{N_j} \right) \quad (8)$$

The configuration term describes the number of combinations of N_j elements out of N choices without repetition. The calculation of Δg_j^0 , the free energy to form a single defect, requires an atomistic consideration (Allnatt and Lidiard, 1993; Kröger, 1964).

If one refers to ionic defects in crystals, it is essentially composed of lattice energy, polarization energy, and vibrational entropy terms. In more general terms, N_j is the number of defects and N the number of particles that can be made defective. Owing to the

Fig. 3 Contributions to the free enthalpy of the solid by defect formation with a constant total number of sites. From Maier J (2004) Physical chemistry of ionic materials. In: *Ions and Electrons in Solids*. John Wiley & Sons, Ltd: Chichester.

infinitely steep decrease of the configurational term with N_j , a minimum in $G(N_j)$ (see Fig. 3) is observed in the elemental crystal; here the chemical potential of j , that is, $\mu_j \equiv \partial G / \partial (N_j / N_m)$, vanishes. Generally it holds that

$$\begin{aligned}\mu_j &= \mu_j^\circ + RT \ln \frac{N_j}{N - N_j} \\ &\simeq \mu_j^\circ + RT \ln \frac{N_j}{N} \\ &\mu_j^\circ + RT \ln \frac{n_j}{n}\end{aligned}\quad (9)$$

($n \equiv N / N_m$, $n_j \equiv N_j / N_m$, N_m = Avogadro's number; $\mu_j^\circ = N_m \Delta g_j^\circ$). It is noteworthy that the strict result (top) which is formally valid for higher concentrations also is of the Fermi-Dirac type. This is due to the fact that one refers to combinations without repetition, that is, double occupancy is excluded and hence the sites are exhaustible similarly as it is the case for quantum states in electronic problems (Maier, 2005; Kirchheim, 1988). (Combinations with repetitions lead to Bose-Einstein distribution.) In a situation in which the levels are broadened to a more or less continuous zone (e.g., electrons in semiconductors and ions in fluids), the parameters N_j and μ_j° of the Fermi-Dirac form have to be attributed to an infinitely small level interval. Denoting the partial free energy level by ϵ , this integral ranges from ϵ_j to $\epsilon_j + d\epsilon_j$ and the total (molar) concentration follows from integration:

$$n_j = \int_{\text{zone}} \frac{D(\epsilon_j) d\epsilon_j}{1 + \exp(|\epsilon_j - \mu_j| / RT)} \quad (10)$$

whereby the molar density of states $D(\epsilon_j)$ appears in the integrand. At equilibrium, μ_j is independent of ϵ_j . Considering without restriction of generality, the almost empty zone and the lower edge of this zone designated as ϵ_j , one can neglect the unity in the denominator of the above equation for all levels more distant from μ_j than ϵ_j' which leads to the Boltzmann expression $n_j \simeq \bar{n}_j(T) \exp(-|\epsilon_j' - \mu_j| / RT)$. The effective value $\bar{n}_j$ is given by

$$\bar{n}_j(T) = \int_{\text{zone}} d\epsilon_j \left[D(\epsilon_j) \exp\left(\frac{|\epsilon_j - \epsilon_j'|}{RT}\right) \right] \quad (11)$$

$\bar{n}_j$ being usually weakly temperature dependent. It is worth noting that, owing to the high dilution, changes of the parameters with occupation have been ignored (for electrons in semiconductors, this is called the "rigid band model"). As anticipated above, the Boltzmann form of the chemical potential results with μ_j° representing an effective value. If n is identified with $\bar{n}_j$, the effective value μ_j° is given by ϵ_j' . As long as one refers to dilute conditions, considerable freedom of normalization is left with respect to the concentration measure. In ionic compounds, charged defects occur pairwise, the formation of which is subject to disorder reactions (and electroneutrality conditions). Then, only the reaction combination of chemical potential vanishes, that is $\sum_j \nu_{rj} \mu_j = 0$ (identical to $\sum_j \nu_{rj} \tilde{\mu}_j = 0$ since $\sum_j \nu_{rj} z_j = 0$), where ν_{rj} is the stoichiometric coefficient of j in the respective disorder reaction r (cf. Fig. 1, bottom). Boltzmann expressions can be written for the individual carriers, if the formation energies and the configuration entropies are considered to be independent. The application of chemical thermodynamics elegantly permits treatment of a variety of ionic and electronic disorder processes that simultaneously occur in a given solid. This is not only possible for the internal disorder equations (such as Schottky, Frenkel, anti-Frenkel, anti-Schottky, electron-hole formation) but also for external reactions such as the interaction of an oxide with the oxygen partial pressure and hence the stoichiometric variation. Under Boltzmann (i.e., dilute) and Brouwer (i.e., two majority carriers) conditions (Kröger, 1964), an adequate expression is arrived at for any charge carrier concentration as a function of the control parameters (temperature T , doping content, component partial pressure P), namely

$$c_j(T, P) = \alpha_j^{\beta_j} P^{N_j} \prod_r K_r(T)^{\gamma_{rj}} \quad (12)$$

($(N_j, \gamma_{rj}, \alpha_j, \beta_j)$ being characteristically simple rational numbers; the total pressure is assumed to be constant.) For multinary compounds (i.e., m components) at complete equilibrium ($m-1$) component partial pressures are to be considered. This solution is only a sectional solution with a window in which the majority carriers situation (Brouwer condition) does not change. The power-law equation defines van't Hoff diagrams characterized by

$$-\frac{\partial \ln c_j}{\partial 1/RT} = \sum_r \gamma_{rj} \Delta_r H^\circ \quad (13)$$

according to which, for not too extended T -ranges (i.e., $\Delta_r H^\circ$, the reaction enthalpy of the defect reaction γ , is constant), straight lines are observed in the $\ln c_j$ versus $1/T$ representation, as well as Kröger-Vink diagrams characterized by straight lines in the plots $\ln c_j$ versus $\ln P$ with slopes

$$\frac{\partial \ln c_j}{\partial \ln P} = N_j \quad (14)$$

Fig. 4 displays the defect chemistry within the phase width of the oxide MO. At low oxygen partial pressure (P_{O_2}), vacant oxygen ions (V_O) and reduced states (e') are in the majority ($2[V_O] \simeq [e'] \gg 2[O_i''], [h]$) (N -regime) whilst oxygen interstitials (O_i'') and oxidized states (h) dominate for very high P_{O_2} ($2[O_i''] \simeq [h] \gg [e'], [V_O]$) (P -regime). At intermediate P_{O_2} , usually ionic disorder

Fig. 4 Internal redox and acid-base chemistry in a solid $\text{MO}_{1+\delta}$ within the phase width at a given temperature T (disorder in the M -sublattice assumed to be negligible).

prevails ($[V_O^{\bullet\bullet}] \simeq [O_i''] \gg [e'], [h^*]$) (I -regime); the alternative situation that electronic disorder predominates ($[e'] \simeq [h^*] \gg [V_O^{\bullet\bullet}], [O_i'']$) is usually scarce. Exactly at the Dalton composition (i.e., at $P_{O_2}^{(i)}$ where $2[O_i''] = 2[V_O^{\bullet\bullet}] = [e'] = [h^*]$), the “nonstoichiometry” δ in $\text{MO}_{1+\delta}$ (i.e., $[O_i''] - [V_O^{\bullet\bullet}] = \frac{1}{2}[h^*] - \frac{1}{2}[e']$) is precisely zero. For $\delta \gg 0$, p -conductors (mobility of h^* usually much greater than for O_i'') are referred to, for $\delta \ll 0$, one refers (mobility of e' is usually much greater than for $V_O^{\bullet\bullet}$) to n -conductors, while at $\delta \simeq 0$, mixed conduction is expected (only if the ionic concentrations are much larger than the electric ones, pure ion conduction results). Usually, the entire diagram is not observed, as there are limits of experimentally realizing extreme P_{O_2} values as well as limits with respect to the phase stability (formation of higher oxides or lower oxides, if not of the elemental metal). Fig. 5 gives three examples: SnO_2 as an oxygen-deficient material, La_2CuO_4 as an example of a p -type conductor, and PbO as an example of I -regime exhibiting mixed conduction. (In PbO , most probably, the counter defect to O_i'' is Pbi rather than $V_O^{\bullet\bullet}$, the results, however, are not different then.) The slopes directly follow from simple mass action considerations

The model example of AgCl shall be considered in more detail. It also exhibits predominant ionic disorder, but now the decisive disorder reaction is the Frenkel reaction of the Ag sublattice (i.e., the formation of silver ion vacancy, V_{Ag}' , and interstitial silver ion, Ag_i). The role of P_{O_2} is played by the chlorine partial pressure. The mass action law for the interaction with Cl_2 reads $[\text{Ag}_i] P_{\text{Cl}_2}^{+1/2} [e'] = \text{constant}$, the mass action constant for the Frenkel reaction being $[\text{Ag}_i][V_{\text{Ag}}'] = K_F$ and that for the band-band transfer $[e'][h^*] = K_B$. Since $[\text{Ag}_i] \simeq [V_{\text{Ag}}'] \gg [e'], [h^*]$, it follows as solution $[V_{\text{Ag}}'] = [\text{Ag}_i] = \sqrt{K_F}$, $[e'] \propto P_{\text{Cl}_2}^{-1/2}$, $[h^*] \propto P_{\text{Cl}_2}^{+1/2}$.

Doping effects

Dopants, i.e. irreversibly introduced structure elements as Cd^{2+} substituting Ag^+ to form the defect Cd_{Ag}' , do not significantly influence the relevant mass action laws, but appear in the electroneutrality relation, here

$$[\text{Ag}_i] + [\text{Cd}_{\text{Ag}}'] \simeq [V_{\text{Ag}}'] \quad (15)$$

Coupling the above relation with the Frenkel equation $[\text{Ag}_i][V_{\text{Ag}}'] = K_F$ leads to

$$[V_{\text{Ag}}'] = \frac{C}{2} + \sqrt{\frac{C^2}{4} + K_F} \quad (16)$$

$$[\text{Ag}_i] = -\frac{C}{2} + \sqrt{\frac{C^2}{4} + K_F} \quad (17)$$

where C stands for $[\text{Cd}_{\text{Ag}}']$. Consider the Brouwer conditions again. For $C \ll \sqrt{K_F}$, the intrinsic result $[V_{\text{Ag}}'] = [\text{Ag}_i] = \sqrt{K_F}$ is obtained. For $C \gg \sqrt{K_F}$, one arrives at

$$[V_{\text{Ag}}'] = C \quad (18)$$

Fig. 5 Three experimental examples of Kroeger-Vink diagrams in a pure oxide MO with ideal defect chemistry. $$[\text{Ag}_i'] = K_F C^{-1} \quad (19)$$

which are immediately obtained by neglecting $[\text{Ag}_i']$ from the electroneutrality relation. Power-law equations are then also valid for the electronic minority carriers in AgCl .

Fig. 6 refers to AgCl and displays the solutions for the ionic defect arrived at by the more accurate equations for both concentrations and conductivities. The different behaviors of defect concentrations and conductivities stem from the fact that the interstitials are more mobile than the vacancies. The introduction of the dopant increases the concentration of the oppositely charged defect and depresses the concentration of the counterdefect according to electroneutrality and mass action. This leads to a decreased ionic conductivity, before the counter defect starts defining the overall conductivity. The conductivity minimum lies approximately at $\sqrt{K_F u_i / u_v}$. Figs. 7 and 8 display the dependence of conductivity on temperature in pure samples and on the doping concentration at given T with regard to positive and negative doping. While the response to Cd^{2+} doping (Cd_{Ag}') follows exactly the predictions (see Figs. 7 and 8), the effect of S^{2-} doping (S_{Cl}') suffers from interaction effects (see below, the absence of a minimum in Fig. 8, LHS, is in qualitative agreement with the fact that $[\text{Ag}_i']$ is increased).

It is clear that for doped samples under Brouwer and Boltzmann conditions, the concentration of any carrier is not only a function of P , T but also of C , and reads (Maier, 2004)

$$c_j(T, P, C) = \alpha_j^{\beta_j} \left(\prod_p P_p^{N_{pi}} \right) C^{M_j} \left(\prod_r K_r(T)^{r_{ij}} \right) \quad (20)$$

(p^{N_j} is replaced by $\prod_p P_p^{N_{pi}}$ in order to allow for multinary equilibria labeled by p). Since

unlike (the in situ parameters) P and T , the variation of C requires a new high temperature preparation, C is designated as an ex situ parameter.

Now this also predicts sectionally constant slopes in diagrams of the type $\log c_j$ versus $\log C$ according to

$$\frac{\partial \ln c_j}{\partial \ln C} = M_j \quad (21)$$

For a simple defect chemistry, the sign of M_j is determined by ("rule of heterogeneous doping")

Fig. 6 Defect concentrations and conductivities as a function of temperature for a fixed Cd-content (a) and (b) and as a function of Cd-content for a fixed temperature (c) and (d).

Fig. 7 Experimental conductivity data for nominally pure and doped AgCl as a function of $1/T$. Here $\lg(\sigma T)$ is plotted instead of $\lg \sigma$ to take account of the slight T -dependence of the prefactor. However, this does not alter the slope noticeably ($\Delta_F H^0$: formation enthalpy of Frenkel defects; $\Delta H_j^{\ddagger}$: migration enthalpy). Fig. 8 The dependence of the conductivity increase brought about by the impurities on the S and Cd content of AgBr. The RHS solid curves are calculated according to the ideal defect chemistry. Reproduced with permission from Teltow J (1949) Zur Ionenleitung und Fehlordnung von Silberbromid mit Zusätzen zweiwertiger Kationen. I. Leitfähigkeitsmessungen und Zustandsdiagramme. *Annalen der Physik* 6: 63–70; © WileyVCH.; Teltow J (1950) Zur Ionen-, Elektronenleitung und Fehlordnung von Silberbromid mit Zusätzen von Silber-, Cadmium- und Bleisulfid. *Zeitschrift für Physikalische Chemie* 195: 213–224; & Oldenbourg Wissenschaftsverlag; © Wiley-VCH.

$$\frac{z_j M_j}{z_d} < 0 \quad (22)$$

which means that, for a positive (negative) doping, the concentration of all negative (positive) defects is increased and all positive (negative) defects are decreased (z_d : charge number of dopant defect). A negative doping is also the reason for the change in the slope from the intrinsic value $-1/6$ to the extrinsic value $-1/4$, in Fig. 5a for SnO_2 , which directly results from the mass action law for oxygen incorporation, that is, $P_{\text{O}_2}^{1/2}[\text{V}_{\text{O}}][\text{e}']^2 = \text{constant}$ (for $2[\text{V}_{\text{O}}] \simeq C$, one obtains $\sigma \simeq \sigma_n \propto [\text{e}'] \propto P_{\text{O}_2}^{-1/4}$ whereas for $2[\text{V}_{\text{O}}] = [\text{e}']$, the result is $\sigma \propto P_{\text{O}_2}^{-1/6}$).

High charge carrier concentrations—Interactions

The above solutions are valid for ionic and electronic carrier concentrations but require low concentrations. One way of correcting interactions is to introduce associates, that is, novel particles formed as the result of these interactions and responding differently to electrical fields or other driving forces. In this way, the scheme of defects is rescaled with the consequence of writing ideal chemical potentials (i.e., interaction free) for these to a better approximation. Examples are interactions of dopants with electronic or ionic carriers (these states appear as midgap states in Fig. 1), associates between electronic carriers (excitons, Cooper-pairs), or between ionic carriers (such as vacancy pairs, interstitial pairs, and Frenkel associates). As an example, the association between Cd_{Ag}' and V_{Ag}' is mentioned that leads to a thermally activated process at low temperatures in the case of CdCl_2 -doped AgCl (lower than those shown in Fig. 7). The more general approach is to include interactions via analytical corrections in the chemical potentials (μ^{ex}) of the charge carriers. (On the level of the concentration, this leads to the activity coefficient as a correction factor.) If the high carrier concentration is a consequence of the high temperatures, such a procedure is indispensable. If it is a consequence of a high doping content, it may be replaced by or better combined with the association procedure. Interactions lead to entropic corrections as well. One of them is obviously due to the exhaustibility of sites (Fermi-Dirac correction). The more detailed account of derivations from a random distribution owing to interactions leads to very complex expressions (e.g., Mayer theory for real gases). Fortunately in the case of weak interactions, the neglect of such entropic corrections is a tolerable approximation. Then, besides possible local vibrational entropies, only energetic nonideality corrections need to be considered. The Debye-Hückel theory (considering each central ion embedded into a diffusive cloud of counter ions, the size being characterized by λ) leads, in the first approximation, to an expression of the form (Allnatt and Lidiard, 1993)

$$\mu_j^{\text{ex}} = RT \ln f_j = - \frac{z_j^2 F^2}{8\pi\epsilon N_m \lambda} \propto c_j^{1/2} \quad (23)$$

that reasonably corrects the chemical potential for low defect concentration. The Debye-Hückel theory proved particularly helpful for electrolytic solutions. At higher concentrations, the corrections become not only complicated but also individual. Here, an ad hoc model that is able to describe interactions in some simple binary crystals and estimate these interactions by assuming that the interaction energy (viz. the structure) can be assessed by a virtual Madelung-superlattice of defects (Hainovsky and Maier, 1995) of the mean lattice constant $\propto c^{1/3}$ is briefly discussed. The prefactor J in $\mu^{\text{ex}} = -Jc^{1/3}$ is determined by Madelung constants of lattice defect, and ground lattice as well as the dielectric constant. The attractive interaction of oppositely charged carriers has the consequence that the formation becomes increasingly easier at high temperatures as soon as the carriers perceive each other in ionic crystals. The conductivity increases in an over-Boltzmann fashion (premelting) and eventually the avalanche effect leads to a phase transformation into the superionic (or molten) state. The order of the transition can be calculated by comparing the

Fig. 9 The “thermal destiny” of an ionic crystal above absolute zero: a progressive development from a perfect to a superionic phase via an ideally defective and a heavily defective state. (a) Crystallographic defect picture and (b) corresponding “energy level” schemes. The indices v and i refer to the vacant regular and interstitial sites. Reproduced with permission from Maier J, Münch W (2000) Thermal destiny of an ionic crystal. *Zeitschrift für Anorganische und Allgemeine Chemie* 626: 264; © Wiley-VCH.

formation enthalpy, the formation entropy, and the interaction strength. Fig. 9 shows the “thermal destiny” of a pure Frenkel disordered binary crystal from the perfect state at low T to the superionic state at high T .

Boundary layers (Heterogeneous doping)

At boundary layers, electroneutrality is no longer fulfilled and space charge regions (width $\sim$ Debye length) occur. The reason for this is the adjustment of structurally different regions. Not only are the electronic concentrations modified, but the mobile ionic charge carriers are also distributed according to the space charge field (both “Fermi levels” are positionally constant). Effects on the ionic conductivity can be immense (Maier, 1995). Double layers formed by the contact of the electrolyte solution to an electrode or charged membrane surfaces in electrophysiology are well-established examples.

Fig. 10 depicts four prototype cases involving solid electrolyte: (1) the contact of an ionic conductor to an insulator, the surface of which is able to trap (internally absorb) ions, leading to the concept of heterogeneous doping (influencing of conductivity by dispersing fine insulator particles is characterized by a similar rule of heterogeneous doping as given above for homogeneous doping obtained; one just has to replace the concentration and charge of the dopant defect by the surface charge density and its sign); (2) the contact of two ionic conductors leading to a charge transfer of ions from one conductor to the other (cf. “ p - n junctions”); (3) charge can also be stored within that core of the boundary, that is, in a grain boundary which joins two chemically identical grains (the effects can be tuned by chemical modification of the boundary or by varying the misfit) and (4) the contact to a fluid, for example, gas phase, acid-base active gases may cause attractive or repelling interactions with mobile ions. Since in many mixed, even in predominantly electronic conductors, ionic charge carriers may be in majority, the ionic redistribution effect may “enslave” the overall electronic boundary concentrations (fellow-traveler effect).

Fig. 11 shows the bending of ionic and electronic energy levels and their interrelation. The determination of the bending effect requires treatment of the chemical thermodynamics of the contact problem and hence a knowledge of energy levels in the interfacial core. In the case of a strong interfacial effect (c_0 : carrier concentration in the first layer adjacent to interface),

$$\Delta\sigma_m^{\parallel} = \frac{u}{L} \sqrt{2\epsilon RTc_0} \quad (24)$$

describes the excess mean conductivity of the mobile majority defect in a Gouy-Chapmann accumulation layer, and

$$\Delta\varrho_m^{\perp} = \frac{1}{L} \sqrt{\frac{\epsilon RT}{2u^2 c_{\infty} F^4 c_0^2 \ln(c_{\infty}/c_0)}} \quad (25)$$

the excess mean resistivity of the mobile majority carriers across a single Mott-Schottky depletion layer situation (dopant with molar charge F and concentration c_{∞}). L is the distance perpendicular to the interface over which the measurement averages. Here and in the following we assume for simplicity that all charges are ± 1 .

Fig. 12 shows heterolayers of CaF_2 and BaF_2 and the effect of the concentration of interfaces on the overall parallel conductance. In a polycrystalline material, bulk and boundary conductivities have to be superimposed according to the microstructural situation. An approximate relation that takes into account the conductivities across ($\perp$) and along ($\parallel$) grain boundaries ($\hat{\sigma}$: complex conductivity; $\hat{\sigma}^{\parallel, \perp}$ refer to the local mean values) is

$$\hat{\sigma}_m = \frac{\hat{\sigma}_\infty \hat{\sigma}_{gb}^\perp + \beta_{gb}^\parallel \varphi_{gb} \hat{\sigma}_{gb}^\parallel \hat{\sigma}_{gb}^\perp}{\hat{\sigma}_{gb}^\perp + \beta_{gb}^\perp \varphi_{gb} \hat{\sigma}_\infty} \quad (26)$$

($\beta^\parallel, \beta^\perp$ refer to the portions of the volume fraction φ that contribute to the path; in the simplest approach, $\beta^\parallel = 2/3$, $\beta^\perp = 1/3$.)

Nano-Ionics

Nano-sized conductors can provide large ionic conductivity anomalies owing to the high concentration of interfaces. Moreover, the spacing of interfaces may be so narrow that they perceive each other (Hainovsky and Maier, 1995; Maier, 2005). Fig. 13a shows the

Fig. 12 Variation of the parallel ionic conductivity of $\text{CaF}_2\text{-BaF}_2$ heterolayers as a function of temperature for different periods (spacings). Fig. 13 (a) Space charge effects decaying with λ . (b) Structural effects which decay rapidly in the bulk, Within the indicated distance (l); the structurally perturbed core (not shown, extension s) is perceived by the defects as far as μ° is concerned. Reproduced with permission from Maier J (2003c) Nano-ionics: Trivial and non-trivial size effects on ion conduction in solids. *Zeitschrift für Physikalische Chemie* **217**: 415–436; © Oldenbourg Wissenschaftsverlag.

space charge overlap occurring in materials when the distance of neighboring interfaces becomes smaller than the Debye length, with the structure being invariant (cf. also Fig. 12). The additional conductivity effects can be described by nano-size factors (Maier, 2005).

If the distance is smaller than the effective thickness of the point defect (i.e., point defect including the sphere of influence in which the structure is perceptibly modified), then the local standard chemical potential changes (Fig. 13b). In the case of delocalized electrons, this may happen at much larger distances. These are only two examples of nanosize effects on ion conduction. Among others, the effects of particle geometry of curvature are mentioned, by which approximately a Gibbs-Kelvin term ($\propto \bar{\gamma}/\bar{r}$; $\bar{\gamma}$: mean surface tension, $\bar{r}$: mean radius) is introduced into the chemical potential if we assume fluid thermodynamics. Such effects do not only affect transport properties, they are also interesting as far as mass storage is concerned.

Partial equilibrium—Bridge between high-temperature and low-temperature situation

Arbitrary deviations from equilibrium require a detailed kinetic treatment. The situations in which some carriers behave reversibly while others are completely frozen are briefly considered here. Such considerations are helpful when the bridge has to be spanned from high-temperature equilibrium (during preparation) to a low operational temperature. In fact, such a partial equilibrium situation was already tacitly assumed when doping effects were studied. At high enough temperatures, dopants become reversible and segregation equilibria become active. Generally speaking, freezing of carriers leads to a reshuffling of in situ to ex situ parameters (i.e., from the P -term to the C -term in the power-law Eq. (20)) (Maier, 2003). The discrepancy between the equilibrium concentration (usually fulfilled at high temperatures under preparation temperatures) and the partially frozen situation becomes apparent in the application of the electroceramics (e.g., high-temperature superconductors and dielectrics) that are used at room temperature. Two aspects are important: (1) a reproducible preparation and (2) a detailed understanding of defect chemistry. For a systematic treatment of these complex problems, the reader is referred to the literature.

Mobility: From low to high concentrations

For dilute concentrations, the mobility in ionic crystals is usually taken to be independent of the concentration. According to the hopping equation ($u_j \propto k_j$), it follows

$$u_j \propto \Gamma_{0j} (\Delta x)^2 \exp \left(+ \frac{\Delta S_j^\ddagger}{R} \right) \exp \left(- \frac{\Delta H_j^\ddagger}{RT} \right) \quad (27)$$

(Γ_0 is the attempt frequency (cf. k_0 , i.e., the prefactor of k), Δx is the hopping distance; $\Delta H^\ddagger$ and $\Delta S^\ddagger$ denote activation enthalpy and entropy, respectively.)

Fig. 14 displays three fundamental hopping mechanisms (Maier, 1993a). While the treatment of the ionic carrier concentrations is, in essence, very similar for liquids or solids, this is less so in the case of mobility. In solids, the activation thresholds of hopping transport are usually substantial (approximately several 100 meV at least), while in dilute liquid electrolytes, temperature effects act on carrier mobilities mainly through changes in the viscosity. At high concentrations, the jump partners in the hopping processes are important which formally leads to the appearance of a concentration factor $(1 - (c/c_{\max}))$ in the mobility. Higher concentrations, however, affect carrier transport in such an individual way that no universal relation can be given and even the decomposition into charge carrier concentration and mobility becomes questionable. For not too strong interactions, a fairly general interaction effect is to be considered. Defect interactions lead to relaxation phenomena in that a particle that has made a jump from x to x' does not directly create its equilibrium environment and has a higher tendency to jump back again. It is, in particular, the rearrangement of the other defects that determines the finite relaxation time. This mismatch situation causes back-jumps to be more likely, making the rate constants of the hopping equation time dependent and hence the conductivity frequency dependent (Funke, 1993). In liquids too, relaxation or better rearrangement effects occur (Onsager, 1927; Barthel et al., 1998). Since the formation of the ion cloud does not immediately follow the mobile ion under regard, the charge cloud becomes asymmetrical and acts as a brake. The relaxation time is proportional to the viscosity. The occurrence of counter transport of differently charged ions which carry along these solvation spheres lead to friction, that is, to a second defect that diminishes the mobility, the so-called electrophoretic effect. These phenomena explain the Kohlrausch's $\sqrt{c}$ law, which is well established for strong electrolytes, and reads

$$\Lambda_c = \Lambda_o \left[\frac{A}{(\varepsilon T)^{3/2}} \Lambda_o + \frac{B}{(\varepsilon T)^{1/2}} \right] \sqrt{c} \quad (28)$$

(A and B are constants, $\Lambda_o \equiv \Lambda_c$ ($c = 0$), ε is the dielectric constant and Λ_c the equivalent conductivity, that is, conductivity per equivalent salt concentration.) (Bockris and Reddy, 1970) Fig. 15 gives some examples of the above phenomena.

Fig. 14 Elementary jump mechanisms in crystals: (a) vacancy mechanism, (b) direct interstitial mechanism, and (c) (collinear or noncollinear), indirect interstitial mechanism (interstitialcy mechanism).

Chemical diffusion in mixed conductors and battery storage

The simultaneous presence of ionic and electronic carriers in so-called mixed conductors leads to the phenomenon of chemical diffusion (coupled transport of ions and electrons) and the possibility of changing stoichiometry (Wagner, 1975). Technologically important examples for which this phenomenon plays a decisive role are insertion electrodes, electrochemical windows, permeation membranes, and conductivity sensors; more generally, chemical diffusion is important for all electroceramics, for their preparation (Schmalzried, 1981, 1995) as well as for their performance that depends on the detailed stoichiometry (such as in dielectrics or superconductors). Stoichiometry changes also occur, if the electrodes applied in the electrochemical measurements are not completely reversible for both ions and electrons; in this case, the partial current density is given by

$$i_j = \left(\frac{\sigma_j}{\sigma} \right) i + z_j F D^\delta \nabla c_j \quad (29)$$

D^δ being the chemical diffusion coefficient that is determined by mobilities and the concentrations of all charge carriers involved in the transport (i : total current density). If different internal reactions such as valence state changes occur for the conducting species, the equation has to be modified (Maier, 1993b). The use of selectively blocking electrodes leads to the suppression of the current of one carrier type at the expense of a concentration polarization. This allows the separation of ionic and electronic conductivities and of the chemical diffusion coefficient. A major application of ion conductors is their use as electrolytes which nullifies gradients in the electrochemical potential of ions but supports gradients in the electrochemical potential of electrons. This gives rise to a cell voltage (e.m.f) which is consequently proportional to the integrated gradient of the neutral component (cf. distance Fig. 2) and

Fig. 15 Equivalent conductivity for a variety of aqueous salt solutions vs. concentration (Λ_c^* and c^* denote unit values). Reproduced with permission from Kortüm G (1972) *Lehrbuch der Elektrochemie*, 5th edn. VCH; Weinheim; © Wiley-VCH.

corresponds to the Nernst equation. In other words, differences in the chemical component potentials can be transformed into an electrical voltage (such as exploited in batteries, fuel cells, and sensors). In mixed conductors, a partial internal short-circuit occurs, causing a nonzero gradient in the electrochemical potential of the ions, which is proportional to the gradient in the electronic Fermi level. Hence, the cell voltage is diminished by a factor (transport number) that depends on the proportion of electronic conductivity and consequently allows for its determination (Maier, 2004; Wagner, 1975; Rickert, 1982).

The kinetics of reaching such a steady state is—if diffusion controlled—determined by the above mentioned chemical diffusion coefficient D^δ . Together with the diffusion distance (L) this value determines the relaxation time of the transients (τ^δ)

$$\tau^\delta \propto \frac{L^2}{D^\delta} \propto R^\delta C^\delta. \quad (30)$$

Writing the product in terms of a chemical resistance R^δ and a chemical capacitance C^δ (Maier, 2004), it becomes obvious that not only the ionic and electronic conductivities are important for the kinetics but also the parameters that determine how much is internally stored. For dilute interaction-free conditions C^δ is determined by the defect concentrations. An important extension refers to including internal reactions as this can change the picture qualitatively. Hence in solids a counter diffusion of two ions that are identical but exhibit different charges (different redox states) translates into an implicit electronic current; in liquids the ambipolar diffusion of ions and their aggregates can pretend (and effectively establish) a diffusion of counter-ions. If the internal reactions are fast, this can be treated within the concept of “conservative ensembles” (Maier, 1993b, 2014). Chemical diffusion also typically describes the kinetics of storage in intercalation batteries (Maier, 2013; Usiskin and Maier, 2018). Unlike usual chemical diffusion processes where a common diffusion source for the component is present, in batteries, ions and electrons are provided from different sites (current collector providing the electrons; electrolyte providing the ions). If this diffusion problem is adequately considered, recipes of how to optimally place these contacts can be derived (see Fig. 16). These so-called optimum wiring lengths ($L_{\text{ion}}^* L_{\text{eon}}^*$) complement the particle size as decisive parameter and allow one to tackle morphological questions in batteries.

Besides intercalation in single-phases, storage e.g., of Li in solid electrodes may involve two- or multi-phase reactions. For the treatment of such phenomena the reader is referred to the literature (Maier, 2013). A conceptually interesting mode concerns interfacial storage in two-phase systems: Space charge effects enable storage at abrupt junctions even in cases where the bulks of the two-phases are not electro-inactive. Here the ion is stored in one and the electron in the other phase. The detailed treatment brings about worthwhile insight (Chen and Maier, 2017; Chen et al., 2016) in terms of: (a) unexpected excess storage, (b) generalization of bulk and boundary storage in that the storage is discussed as a function of position coordinate, and (c) unification of bulk and supercapacitive storage with the possibility of generating artificial electrodes.

As far as the kinetics are considered, bulk pathways become important but also diffusion along the space charge zones. The latter is characterized by “heterogeneous” chemical diffusion coefficients which may exhibit extremely high values.

Fig. 16 In the case of Li-storage the ions are delivered by the electrolyte and the electrons by the current collector. The particles should be small to enable fast storage. How intimate the electronic or ionic contacts have to be, can be deduced from the partial conductivities. Here predominantly electronically conducting electrode particles are assumed. Fig. 17 Sketch of a membrane. Its electric potential derives from the charge imbalance stemming from osmotic effects. Its selective permeability relies on the functions of ion channels and ion pumps and sensitively depends on the membrane potential itself.

Ion transport in biology

Ion transport is also crucial in biology (Kandel et al., 2000). In relevant cells channels and pumps lead to ion leakage, or active transport of ions by using biological energy conversion (ADP/ATP). These functional elements are important e.g., in the process of photosynthesis but in particular for the generation and transmission of nerve signals. The fundamental process is the generation of a membrane potential. This membrane potential is due to the membrane's selectivity. The membrane allows the transport of a given ion but precludes the transport of others. Hence an electric potential is generated if the membrane separates two chambers of different salt concentrations. (It is revealing to compare this with the generation of a battery potential). Here the electrolyte shows selectivity concerning transport of ions versus transport of electrons. The latter is precluded and a voltage generated if the electrolyte membrane separates two chambers of different chemical component potentials. What distinguishes such biological systems from usual electrochemical systems is the chemical complexity and—not independent from it—the non-linearity of the flux-force relation. The latter is achieved by the variation of the membrane conductivity (selectivity) on varying the stimulus, e.g., the voltage. Applying a certain electric potential results e.g., in opening or closing of specific ion channels which eventually leads to what is called an action potential. Fig. 17 refers to a typical situation at a membrane of a nerve cell.

The non-linearity is also responsible for the nerve-signal transmission within the neuron. The transmission from one neuron to the next occurs via synapses. The “plasticity” of the synaptic action is highly important for learning effects in the brain.

In physics mostly electronic transfer and transport is considered. The sheer concentration on it, i.e., ignoring ion transport forbids a proper treatment of mass transport in ionic materials, compositional changes and electrode storage phenomena. The article traces ion transport back to the basic mechanistic centers as well as to the basic phenomenological relations. It deals with bulk as well as interfacial phenomena. Reducing the size co-ordinate leads to phenomena in the realm of nanoionics which is expected to be of similar importance for basic research and application as nanoelectronics. Taking seriously the chemistry allows one also to get a hold on the complexity co-ordinate, and thus also to achieving a better understanding of electrophysiological processes.

Conclusion

The significance of ion transport in condensed matter is threefold:

- (1) It is key to the understanding of electrochemical processes ranging from battery research to nerve-signal propagation.

- (2) The combination with electron transport enables compositional changes. Typical examples are stoichiometric changes within the condensed phases as a consequence of the interaction with ambient phases.
- (3) Even if one concentrates on electronic effects such as electronic resistance or electron redistribution at interfaces, the role of ion motion ions is very often decisive and may even dictate the electronic situation.

The contribution summarizes the fundamentals of ionic charge carriers with emphasis on the solid crystalline state; it reveals isomorphies and differences between ionic and electronic charge carriers on one side and between solid and liquid state situations on the other.

Abstract

This article provides an overview of and general introduction to the present understanding of the electronic structure of liquids. Special emphasis is laid on the role played in recent years by ab-initio simulation methods to get insight into the strong interplay between electronic and structural properties typical of the liquid state. Discussion of physical systems is organized around the illustration of few selected results for prototype classes of liquid systems corresponding to the five types of electronic bonds: metallic, covalent, ionic, hydrogen, and van der Waals.

Key points

- The electronic structure of liquids is strongly linked to the average atomic positions in a self-consistent way.
- Classification of the electronic properties of crystalline solids can be directly adapted to the case of liquids by eliminating the features more related to spatial periodicity.
- Key quantities for describing the properties of electronic structure are the space-dependent electronic density and the electronic density of states (e-DOS).
- The electronic density directly controls interatomic interactions.
- Recent advances in ab-initio numerical simulation methods allow a description of the electronic structure of liquids equivalent to that of solids.
- This chapter aims to provide an overview of the present understanding of the electronic structure of liquids by focusing on a few selected results for prototype classes of liquid systems.

[☆]*Change History:* May 2023. Author involved in preparing the update G Pastore. All the sections and the figures of the articles have been updated, although the original organization of the article around the different types of binding in condensed matter has been kept. Relatively minor changes have been introduced in the sections on Simple metals, Expanded liquid metals, M/NM transition, Excess electrons, molecular liquids, and metallization under pressure.

*Deceased.

Nomenclature

e	electron charge
e-DOS	electronic density of states the number of one-electron states per unit energy and volume
$\hbar$	Planck constant h -crossed (h divided by 2π)
k_B	Boltzmann constant
k_F	Fermi wavenumber
m	electron mass
M/NM	metal nonmetal
$V_{ij}(k)$	product of the electron-ion pseudopotentials of two ions of species i and j
x_i	concentration of the species i
z	ionic valence
Δ	nonadditivity parameter
ϵ_0	vacuum dielectric constant
$\epsilon(k)$	static dielectric function
κ	thermal conductivity
ρ_e	electric resistivity
σ_i	effective diameter of an ion of species i
$\phi_{ps}(k)$	Fourier component of the electron-ion pseudopotential
$\phi(r)$	effective ion-ion pair potential

Introduction

The electron distribution in a material directly controls interatomic forces, and thus the atomic structure of a material. At laboratory temperatures and pressures, part of the electronic structure, the innermost atomic shells in a one-electron description, is practically unaffected by changes in interatomic distances and chemical environment. Another part, the valence electrons, is directly involved in forming bonds, and then it plays a double-face role. At the same time, it affects, and it is affected by the nuclear positions in a self-consistent way.

In the case of crystalline solids, such a link between structure and interactions can be partially broken by exploiting the simplified description of the atomic positions in periodically repeated units. Liquids, with their intrinsic high atomic mobility, present a broader range of possibilities for atomic positions, inducing dramatic modifications of the average electronic configuration as a function of a pressure, temperature, and composition. Distinct features of liquid phases, important for their role in determining the electronic properties are highly individual and collective ionic mobility, a time scale of ionic dynamics much shorter than the time scale of electronic relaxation, the absence of long-range order but the presence of short-range order with a continuous distribution of interatomic distances and angles.

From the experimental and theoretical side, studying the electronic structure of liquids does not introduce fundamental differences with the case of amorphous solids, while we have to renounce to many of the solid-state techniques directly related to the translational symmetry of crystalline structures. However, the evolution of experimental and numerical simulation techniques has provided a partial compensation, resulting in a much more accurate description of disordered phases than in the past. Still, some concepts play a central role for all condensed systems. An example is the electronic density of states (e-DOS; the number of one-electron states per unit energy and volume). Although based on the introduction of approximate one-particle wavefunctions, it is a quantity of primary interest for discussing electronic properties in many condensed systems. Other examples include the dipole-moment distribution or the local net charges around ions, helpful to rationalize experimental results.

The differences between disordered and ordered phases should not make us forget that a previous knowledge of the properties of crystalline phases may be useful to understand the disordered phases. Indeed, at a local level, there are some important similarities between liquid and solid phases. The reason is the relatively small difference in the coexisting solid and liquid density, usually not larger than a few tens of percent. Thus, the resulting variation of the interatomic distances at melting is usually small. Thus, a useful way to open an overview on the electronic structure of liquids is to recall the five types of crystal binding: metallic, covalent, ionic, hydrogen, and van der Waals bonding.

It stands to reason that the electronic structure of a metal is essentially unchanged on melting. In metallic liquids, the e-DOS, although blurred due to the lack of long-range order, still has significant values at the Fermi energy, providing a mechanism for typical metallic conduction. In parallel with the case of metallic crystals, the e-DOS of liquid metals goes from a recognizable modification of the uniform electron gas behavior in the case of the alkali metals, to more significant deviations for polyvalent sp-bonded metals, to the qualitative modifications due to the contributions of the d and f states in transition metals and rare earths.

As a consequence of density changes or by varying the composition in mixtures, a rapid departure from a purely metallic behavior up to the catastrophic metal/nonmetal (M/NM) transition may appear, with the system always remaining in the fluid phase.

In contrast to metals, dramatic changes in the electronic structure occur on melting in some covalent elemental systems such as B, Si, Ge, and 13–15 (III–V) compounds: the covalent bonds collapse into a metallic state, though with some peculiarities of its own. These elemental melts can be brought into an amorphous state by rapid quenching, just as those of other covalent compounds such as SiO₂ or GeSe₂ whose liquid structure is best described as a disordered covalent network.

Pure covalent binding is characterized by a gap in the e-DOS between occupied and empty states, and by a higher localization of valence electrons between ions. The resulting interatomic interactions have a quite strong dependence on the mutual orientation of neighbor ionic pairs as measured by the angle between triples of atoms. Therefore, the resulting interactions cannot be reduced to pairwise force fields, and three-body or four-body terms are required.

A typical example of ionic binding in liquids is the case of molten salts. Typical gaps between occupied and empty states in the e-DOS are higher than in covalent systems, but their distinguishing feature is the presence of at least two atomic species with a great difference in electronegativity. Electrons from the less electronegative atom move toward the more electronegative and, in the limiting case of alkali halides, the topmost s electron of the alkali is almost entirely transferred to the halide ion. Such a feature clearly visible in experimental measurements of the electronic density in the solid remains when the solid melts, although the larger range of distances in the liquid induces some deformation effect (polarization) of the electronic density around the ions. In some cases, the state of aggregation of the ions may drastically change. For example, AlCl_3 melts from a layer structure where the Al ions are sixfold coordinated into a liquid of Al_2Cl_3 molecular dimers showing fourfold coordination of Al. The presence of chemical order in these melts can favor the acceptance of foreign electrons inside the liquid structure, as in mixtures with metals that may be stable over a wide range of concentrations.

The cases of van der Waals interactions are not only typical of rare gases but are also typical of closed-shell molecules and of the hydrogen bond. They share with the stronger ionic binding the characteristic of being only marginally perturbed on melting, requiring only, as a first approximation, to take into account polarization effects. The reason for such stability can be traced to the stability of closed shell structures, for van der Waals fluids, to the special role of the hydrogen cation (a proton) in polarizing the shell of valence electrons of near atoms in the case of hydrogen-bonded fluids.

In addition to the characteristic electronic structures of the above-mentioned classes of liquids we will briefly mention the case of localized states of excess electrons, historically one of the oldest topics in the electronic structure of liquids. The article ends with a brief section of conclusions and an outlook.

Experimental and theoretical methods

Before discussing recent progress in the understanding of the electronic structure of different classes of systems, it is worthwhile to briefly recall how such properties can be measured and what are the main theoretical tools and their recent evolution.

On the experimental side, photoemission spectroscopy remains one of the main techniques to directly probe the e-DOS of condensed phases, liquids included. Information on the atomic positions is usually obtained from scattering experiments. In the case of bulk liquids, mainly X-ray and elastic neutron scattering are routinely employed. The resulting information is encoded in the atomic pair radial distribution functions or their Fourier transforms, the atomic structure factors. Such quantities provide only statistical information about atomic positions, constraining them but not providing explicitly three-dimensional atomic coordinates. In combination with X-ray absorption spectroscopy (XAS) and theory and simulations, elastic scattering data may provide quite a detailed description of the average local structure in disordered phases.

In recent years, new methods have appeared, in particular, ultrafast spectroscopy, specially tailored for typical transient phenomena in the liquid state. An example of the potentialities of such techniques is the recent study of the possible liquid–liquid phase transition in silicon (Beye et al., 2010).

On the theoretical side, approximate theories of the electronic structure of liquids have evolved, mainly during the nineties, to a stage where at least for sp-bonded liquids, it is possible to get quite accurate self-consistent calculations of the atomic structure and e-DOS at the same time (Stratt, 1990). One interesting approach is based on a combination of a tight-binding description of the electronic interactions and the Ornstein-Zernike (OZ) integral equation description of the pair correlations in the atomic structure (Hansen and McDonald, 2013). The resulting theory, formally similar to the integral equation theory for the liquid structure, allows the numerical calculation of reliable and accurate e-DOS as compared with simulation results for s- and sp-bonded liquids (López-Martín et al., 1997).

Probably, the most important progress in the last decades has come from simulation methods with the progressive establishment of Ab-initio Molecular Dynamics (AIMD) techniques, like Car-Parrinello (Car and Parrinello, 1985) or Born-Oppenheimer algorithms (Hutter, 2012) as a standard for numerical calculations of equilibrium properties for liquids. AIMD simulations are currently based on the Density Functional Theory (DFT) of the electrons (Martin, 2020), thus shifting the focus from wavefunctions to electronic density. The main idea behind AIMD, introduced for the first time by Car and Parrinello is to combine the numerical integration of classical equations of motions for the atoms with a calculation on-the-fly of the interatomic forces, based on an efficient updating of the DFT-based electronic density at each time step. A key ingredient of many AIMD calculations is the introduction of ab-initio electron-ion pseudopotentials designed to reproduce with the maximum accuracy the scattering properties of the frozen-core ions in a suitable interval of energies. Introduction of pseudopotentials dramatically reduces the number of dynamical variables of the simulations without introducing uncontrolled approximations.

Classical trajectories of the atoms resulting from forces due to ionic cores and quantum electrons can be evaluated, and used to compute time averages of physical properties. At variance with Molecular Dynamics based on empirical force fields, AIMD methods do not introduce additional approximations on the interactions beyond the Born-Oppenheimer partial decoupling between ionic and electronic components, the frozen core approximation for electrons, and the classical treatment of ionic dynamics. Moreover, based on the solution of the quantum electronic problem, AIMD provides direct and self-consistent information on the electronic structure. At the one-electron theory behind the usual Kohn-Sham implementation of DFT, the one-electron energy spectrum can be used to evaluate the time-averaged e-DOS.

Using more ambitious techniques like time-dependent DFT (TDDFT) (Marques et al., 2006) and Quantum Monte Carlo algorithms (Becca and Sorella, 2017) is progressively increasing, even though they are at a less mature stage as general-purpose simulation methods, and do not allow direct calculations of atomic dynamical properties.

Metallic liquids

Simple metals

The simplest liquid metals are one-component systems made of atoms with only s and p valence electrons. In correspondence with the first column of the periodic tables (alkali metals) the interaction between the ionic cores and valence electrons is relatively weak, and this is reflected in weak pseudopotentials. For such systems, second-order perturbation theory of the uniform electron gas in powers of the electron–ion pseudopotential provides good results for electronic and structural properties, in quantitative agreement with more precise calculations.

By introducing the Fourier component of a local (i.e., independent of the angular momentum value) electron–ion pseudopotential $v_{ps}(k)$, and perturbing with it a homogeneous, interacting electron gas, characterized by a static dielectric function $\epsilon(k)$, we can obtain an effective pairwise interatomic potential from second-order perturbation theory (March, 1990)

$$\phi(r) = \frac{z^2 e^2}{4\pi\epsilon_0 r} + \frac{1}{2\pi^2} \int_0^{+\infty} \frac{\sin(kr)}{kr} \hat{\phi}_{ps}(k) k^2 dk$$

where

$$\hat{\phi}_{ps}(k) = \frac{1}{e^2} \left(\frac{1}{\epsilon(k)} - 1 \right) v_{ps}^2(k).$$

Here, z is the ionic valence, e is the electronic charge, and $\epsilon(k)$ is the static dielectric function of the interacting electron gas. The qualitative behavior of such pairwise interaction is shown in Fig. 1. The characteristic oscillations of wavenumber $2k_F$ are related to the nonanalytic behavior of the dielectric function of the ideal Fermi gas at the Fermi momentum. The atomic structure factors obtained from these interactions are in excellent agreement with elastic scattering experiments.

The adequacy of a perturbative approach in the case of alkali metals is also confirmed by the success of the simple diffraction theory by Ziman (Ziman, 1961) to account for electric resistivity, dominated in the metals by the electronic contribution. Ziman's theory allows us to calculate the electric resistivity within the same linear response theory used to account for the electronic density, interatomic interactions, and Thermodynamic properties. The electronic contribution is also dominant in the thermal conductivity κ of the metals. Indeed, the Wiedemann–Franz law asserts that the quantity $\rho_e \kappa / T$, where ρ_e is the electric resistivity and T is the absolute temperature, is a universal constant, the Lorenz number, $L = \pi^2 k_B^2 / 3e^2$ where k_B is the Boltzmann constant. Empirically, this law is satisfied by many liquid metals near freezing, within a scatter of about $\pm 10\%$. The electronic contribution is minor in simple liquid metals' shear and bulk viscosities.

A more demanding case for perturbation theory is the calculation of the properties of alkali metal alloys. They can be satisfactorily described by perturbation theory only in the case of the simplest case of Na-K alloys. An example is provided by the results of the calculation of the electric resistivity using the extension of Ziman's theory to the alloys, resulting in the following approximate formula

$$\rho_e = \frac{12\pi m^2}{\hbar^3 n e^2 k_F^2} \int_0^1 \left[\sum_{ij} x_i x_j |V_{ij}(k)|^2 S_{ij}(k) \right] \cdot \left(\frac{k}{2k_F} \right)^3 d\left(\frac{k}{2k_F} \right).$$

A comparison of theoretical and experimental results for the isothermal variation of resistivity with the concentrations is shown in Fig. 2 (Pastore et al., 1981).

The excellent agreement obtained in this case progressively degrades in other binary alkali metal alloys. The reason for such a failure of the perturbation approach can easily be understood. Sodium and potassium pseudopotentials are the closest among the

Fig. 1 Qualitative behavior of the effective pair potential (multiplied by $\beta = (k_B T)^{-1}$). Notice the damped Friedel oscillations related to the non analyticity of the electronic dielectric function at the Fermi wavenumber.

Fig. 2 Electric resistivity of the Na-K liquid alloy at 100°C versus potassium concentration. Full curve: theoretical results from perturbation theory and Faber-Ziman formula (see text); dots: experimental results from Hennephof et al. (1978).

alkalis. The increasing difference in electro-ion interactions in other alkalis makes the local environment of an atom in a mixture farther from that in pure liquids. Such a difference would require more transferrable pseudopotentials, but a higher transferability is accompanied by an increase in the strength, making second-order perturbation less accurate.

Polyvalent metals

Moving away from the first column elements, increasingly stronger deviations from the free-electron approximation are also a consequence of stronger electron-ion pseudopotentials. Moreover, in the case of transition metals, the presence of incomplete 3d, 4d, and 5d shells introduces sharp features in the broad sp bands. Taking into account the limitations of perturbation theory, AIMD was expedient in shading light on the ionic and electronic properties of polyvalent liquid metals and their alloys in disordered phases.

As an example, in Fig. 3, we can see the contour plot of the electronic density in a plane containing three magnesium atoms in a single configuration of an AIMD simulation for pure liquid magnesium at 1000 K (De Wijs et al., 1995).

The contour plot of the total valence density in the left panel of the figure shows a spatial modulation with a maximum gradient around the ions. The apparent plateau of density close to the nuclear position is the effect of plotting the valence density only. If included, the contribution to the electronic density from the core states density would dominate the region around nuclei. The right panel nicely illustrates the poly-center nature of the metallic bond. Part of the atomic density has been transferred to the interstitial region between the ionic cores without a strong localization.

The general agreement between experimental values and AIMD calculations of physical properties of polyvalent liquid metals, including transition metals, is in general excellent.

In the case of the heaviest elements, relativistic effects play an essential role and should be taken into account in DFT calculations. Not only are such effects responsible for important changes in the gap values of the e-DOS, therefore modifying the optical properties with respect to nonrelativistic calculations, but, as it has been recently shown, they play an essential role in ionic and thermodynamic properties. As an example, AIMD calculations have shown that the melting point of Mercury at normal pressure would be more than 150 K higher, making this metal a solid at room temperature (Steenbergen et al., 2017).

Fig. 3 Left panel: contour plots of the electronic density in liquid Mg at 1000 K from a single configuration of an AIMD simulation (De Wijs et al., 1995). The three black dots indicate the position of three Mg atoms. The iso-density lines are drawn at a density spacing of 13.5 electrons/nm³. Right panel: difference between the self-consistent ground state density shown in the left panel and the superposition of isolated atom densities. Dashed lines indicate negative values. Contours are traced at a spacing of 6.75 electrons/nm³.

As a general rule, relativistic effects on the electronic structure act at two different levels. On the one hand, spin-orbit effects tend to increase the gaps in the e-DOS, like in the solid phases. Moreover, a different effect is related to the contraction of the core shells, with an indirect effect on the valence electrons via the pseudopotentials. Notice that such effects are not limited to metallic systems.

Expanded liquid metals and M/NM transition

Extensive work done in the past (Hensel and Warren, 2014) and also recently (Pilgrim et al., 2018) on expanded mercury and liquid alkali metals (the metallic elements with the most accessible critical point) has shown how closely the electric transport properties of expanded liquid metals depend on the properties of the electron gas as a function of density. By decreasing density, the screening is weakened, and electrons are more easily localized in a scenario consistent with Mott's model. A typical variation of electric resistivity with the density in such systems is shown in Fig. 4. Data are plotted as a function of the reduced density $\phi = \frac{\rho - \rho_2}{\rho_1 - \rho_2}$, where ρ_1 and ρ_2 are the density of the metallic and nonmetallic phases, respectively. Data from Ruland and Hensel (2010).

A density threshold is evident, separating a high conductivity phase, at higher densities, from a low (but not zero) conductivity at low densities. The present experimental evidence indicates that the M/NM transitions occur with a decomposition of the metallic liquid into a two-component mixture of conducting and nonconducting domains. Such a decomposition seems to accompany the liquid–vapor coexistence in the case of liquid alkali metals. The coordination number of a Cs atom that is obtained from the data by extrapolation to the critical density approaches the value 2. This suggests that, as the metallic fluid is driven toward a metal-insulator transition, chainlike structures are stabilized by chemical bonding and probably coexist with small clusters such as ionized dimers. On the gas side of the critical point, one finds a large number of diamagnetic units such as Cs_2 molecules and probably larger clusters.

Different scenarios are possible, accordingly to the hypotheses proposed initially by Landau and Zeldovich (discussed in Hensel (2010)). A first-order M/NM phase transition could occur wholly in the liquid or vapor phase or on the continuation of the coexistence line above the critical temperature and pressure. Although a definite conclusion is still missing, work on such a topic is in progress.

Metallic alloys

Metallic liquid alloys show a much larger variety of behaviors than pure components. Differences of electronegativity, with the resulting partial electron transfer from one species to another, allow a vast set of possibilities for electronic and, consequently, ionic configurations. Almost all the metallic binary alloys show a clear indication of nonadditivity of the excluded volumes around the ions. This is visible on the partial radial distribution functions $g_{ij}(r)$ obtained from the Fourier transform of the k -dependent cross-section from the elastic scattering of X-rays or thermal neutrons.

If we quantify the radius σ_{ij} of the volume around a particle of species i excluded for particles of species j by using the position of the first peaks or from other reasonable estimates like the distance where each $g_{ij}(r) = 1$, in general we can write

$$\sigma_{12} = \frac{\sigma_{11} + \sigma_{22}}{2} (1 + \Delta).$$

with a nonadditivity parameter (Δ) positive or negative. Positive values of Δ imply a local tendency toward homo-coordination and the possibility of a demixing phase transition as a function of the state. Negative values correspond to a tendency toward etherocoordination and enhanced stability of the mixed phase. Such a local tendency may be increased or decreased by long-range interactions. Therefore, for many liquid alloys, a parallel study of the size nonadditivity, and the charge transfer due to the electronegativity differences may help to predict their solubility properties.

Fig. 4 Experimental behavior of electrical conductivity of expanded fluid mercury as a function of the reduced density ϕ (see text for definition). Data from Ruland W and Hensel F (2010) Critical region and metal-nonmetal transition in expanded fluid mercury: Advanced evaluation of small-angle X-ray scattering data. Journal of Applied Crystallography 43 (2): 244249.

In some cases, the analysis of the corresponding solid phases has suggested the persistence in the liquid phase of some peculiar atomic structures stabilized by the electronic structure.

An interesting example of this can be found in the case of the so-called Zintl phases. In the 1930s, the inorganic chemist Zintl proposed a powerful interpretation principle for a class of intermetallic compounds. The principle can be applied to ionic alloys with a large difference in electronegativity, like alkali-group 14 (IV) elements. In such alloys, each alkali cation loses its valence electron, while negatively charged anions become isoelectronic to P or As, which form in the gas phase, tetrahedral P_4 and As_4 clusters. Indeed, negative anions form ionic tetrahedra clearly identified in the crystalline phases. All the crystalline phases of equimolar alloys show isomorph or closely related atomic structures. In the liquid phase, these alloys exhibit special behaviors, like the resistivity maximum and dips in the alkali Knight shift as a function of composition, suggesting the presence of such clusters in the liquid phase, causing a depletion of electrons at the Fermi level. A piece of indirect evidence was obtained from the analysis of the partial structure factors of the liquid. In particular, the presence of a prepeak in the total structure factor is usually a signal of intermediate-range ordering due to the clusters.

Only after the development of AIMD methods was it possible to validate the Zintl model based on a careful analysis of the ionic configurations obtained from a consistent treatment of the electronic states. Numerical simulations of these alloys have provided evidence for the correlation between preferred atomic configurations and electronic properties of the model, albeit with more complex details. In the solid structures of equimolar alloys, the separation between bonding and antibonding states is reflexed by a minimum or a gap in the e-DOS. AIMD calculations have shown that even if perfect tetrahedra are destroyed by the thermal ionic motion, tetrahedral coordination and angle distribution remain close to the tetrahedral values. Thus, the naïve model with perfect tetrahedral Zintl ions should be modified into a more complex scenario characterized by the presence of fluctuating clusters of fourfold coordinate atoms, coexisting and merging with other clusters, still keeping an electronic e-DOS qualitatively amenable to the ideal e-DOS of a structure made of perfect tetrahedra. Indeed, the analysis of the electronic ground state of an s-p tetrahedral cluster like P_4 shows that the p levels, quite far from the s levels, are split into four full low-lying bonding states and two empty high-lying antibonding states. The e-DOS averaged over many ionic configurations is consistent with the analysis of the energy levels of the isolated cluster and calculations on crystals. The case of CsPb is shown in Fig. 5.

Three bands are visible. The lowest lying band is due only to the Cs 5s states. The double peak band around -10 eV is due to hybridized Cs 5p states (the peak on the left) and Pb 6s states (a broad peak from -11 to -6 eV, with an absolute maximum at the position of the subpeak on the right). The third visible band, starting below -2 eV, has a local minimum close to the Fermi energy (E_F) with an essential contribution from the d states of Cs. Such a minimum of the e-DOS is consistent with a semiconductor-like behavior of the electric resistivity.

Zintl ions are not the only example of characteristic electronic structures due to the presence of complexes in the liquid. Anomalies in all the electronic properties related to compound formation have been reported at the electronic octet composition, in the case of Li_4Pb and Li_4Sn , or at equimolar composition for CsAu.

Electron-ion correlations

In a crystalline solid, X-ray scattering can directly provide information about the electronic density distribution around the nuclei. In a liquid, the atomic motion does not allow a direct measurement. However, looking at the system as a two-component system of ions and conduction electrons, and following a quite old proposal by Egelstaff, it should be possible to combine different scattering techniques to obtain separate contributions coming from the electron-electron, electro-ion, and ion-ion correlations.

Takeda's group carried out some pioneering efforts in such direction for several liquid metals combining neutron and X-ray scattering with theoretical results for the electron-electron correlations (Takeda et al., 1996).

Fig. 5 e-DOS of CsPb liquid alloy at 1050 K. Data from 10 liquid configurations have been averaged and smoothed.

AIMD provided a computational tool for studying electron-ion correlations. An early attempt in this direction was made for liquid Mg and Bi, and additional studies have demonstrated the feasibility of such computational approach. The combination of experiments and AIMD could be instrumental to get insight into the electronic distribution and, indirectly, to assess the quality of different density functionals and pseudopotentials. However, the present status of such an approach (Anta et al., 1998) is that the quantitative discrepancies exist between simulation and experimental results, suggesting the need for improvements in the corrections in data analysis of both neutron and x-ray scattering measurements.

Liquid semiconductors and insulators

Molten semiconductors

A sharp distinction between liquid metals and liquid semiconductors is difficult. In practice, an arbitrary border is conventionally put at values of the electrical conductivity σ larger than $2000 \Omega^{-1}\text{cm}^{-1}$, corresponding to the threshold where, in the free electron model, the mean free path of the electrons becomes comparable with the interatomic distances. However, no sharp transition is observed experimentally, if it is not accompanied by significant structural rearrangements. Semiconducting group-14 (IV) elements and 13–15 (III–V) compounds, at their melting point under normal pressure, increase both density and coordination numbers, thus going to more compact structures characterized by metallic conductivity.

Such a general scenario is declined differently in different systems. Crystalline archetypal semiconductors like Silicon and Germanium are found in the open fourfold coordinated diamond structure up to their melting point. The corresponding liquids have coordination between 6 and 7 and are metallic. Therefore, melting is accompanied by a partial release of the valence electrons from interatomic bonds into less localized conducting states. Liquid silicon was the subject of one of the first applications of AIMD to the liquid state. Analyses of the electronic density between nearest neighbors strongly suggested a continuous change of bonding character as a function of the atomic distance.

Just below their melting point, Selenium and Tellurium are semiconductors in hexagonal crystalline structures where atoms are arranged in infinite helical chains. After melting, liquid Selenium remains a semiconductor with a structure characterized by the persistence of long chains (about 10^5 atoms) with coordination close to two. On the contrary, liquid Tellurium is metallic. Surprisingly, it shares with water a few anomalies, notwithstanding the entirely different kind of binding: covalent bonds in Te, and hydrogen bonds in the case of water. Below the melting point, extrema are present in specific heat, isothermal compressibility, and thermal expansion coefficient of Tellurium. Close to the melting point ($T = 722$), there is a density maximum. DFT calculations have shown that disruption of Te chains requires less energy than Se chains. As an effect, the liquid structure of Te and then its electronic properties are strongly affected by a rapid change in the chain length and by the presence of two-fold and threefold coordinated atoms, rings, and cavities.

Molten salts

The simplest molten salts are represented by the alkali halides, where the large electronegativity difference is responsible for the almost complete transfer of the unpaired s electron of the alkali to the anion. We have direct evidence of that from experiments in the solid state, and an indirect evidence by the good performances of purely ionic models for energy and structural properties of the solid and molten phases. Still, the agreement is not complete, and the polarization effects of the ionic electronic shells are deemed to account for about 10% of the cohesive energy and turn out essential to bring numerical calculations in quantitative agreement with structural data from scattering experiments.

The liquid structure of alkali halides characterized by strong short-range chemical order: each ion is surrounded by a well-definite screening shell of oppositely charged first neighbors.

Moving toward a smaller difference in electronegativity, polarization effects (mainly in the anions) become increasingly important, and become the key ingredient to understand local order and its variation with the thermodynamic state in many molten salts.

Like in the case of intermetallic compounds, many molecules with a strong ionic character show a persistence of their molecular properties in the molten salt phase. The main questions about the electronic structure in such ionic conductors are about the modifications of the electronic states induced by the disordered condensed phase and, in particular, the possible modifications of the electronic and structural properties under pressure. Again, combining experimental techniques and AIMD methods allows us to gain insight into this fascinating subject (Brazhkin et al., 2007).

Excess electrons, molecular liquids, and metallization under pressure

A problem that has garnered interest for its relevance for many radiation chemistry problems and for many applications, for example the high-energy particle detectors, is the description of the electronic states of excess electrons in dielectric liquids. Recent research agrees on a general scenario where electrons relax to localized cavity-like structures. The study of the relaxation process and the possibilities of reaction of the solvated electron in the host liquid strongly depend on the material and research in this field could recently take advantage of developments in experimental (Herbert and Coons, 2017) and simulation (Marsalek et al., 2012) techniques.

Molecular liquids maintaining the presence of stable closed-shell molecular units are insulators. Their electronic properties are mainly related to dipole moments and electric polarizability. The range of the observed behavior is quite broad, from molecular liquids of apolar diatomic molecules to the case of strongly polar molecules, including hydrogen-bonded molecules. From the point of view of the electronic structure, an interesting problem is understanding the mechanism underlying molecular unit evolution and its consequences on the physical properties under pressure. In a way, it is the high-pressure-side counterpart of the M/NM transition.

Recent high-pressure studies have reached several hundred gigapascals, corresponding to free-energy variations larger than 10 eV, exceeding the binding energy of the strongest covalent bonds. Thus, under very high pressure, significant bond changes may appear, affecting almost all physical properties. For such reasons, High-pressure Physics has become an important laboratory for studying the variation of electronic structure and its consequences.

Not all materials behave in the same way under pressure. Alkali metals are deemed to undergo a dimerization, forming an insulating phase under pressure before a final metallization at even larger pressures. Some molecules remain stable under relatively high pressures. For example, liquid iodine shows an increase in the bond length under pressure and indications of molecular dissociation close to 4.5 GPa and 1000 K. The metallization in the liquid phase shows some puzzling features. The most important is its appearance in the liquid phase at a lower pressure than in the solid phase. In both phases, the abrupt drop in electric resistivity with increasing pressure occurs before the molecular dissociation.

Probably the most challenging case of metallization of a molecular liquid is the case of hydrogen, both for its unique behavior making it more similar to halides than alkali metals and for the relevance of results for many astrophysical problems. Hydrogen has a very rich phase diagram, notwithstanding the simplest structure of the atom. In standard laboratory conditions, cooling the gas of diatomic molecules brings it into a liquid of weakly coupled molecules and then into a crystal, in which the molecules are rotating with weak hindrances from each other. Compression at low temperatures brings the crystal into a new phase, in which the molecular rotations are hindered and ultimately into a further crystal phase whose strong infrared activity indicates a mainly dipolar distortion of the electronic distribution. Molecular dissociation can occur as hydrogen is brought into the regions of high temperatures and densities relevant to astrophysics. Dynamic experiments under pressure have provided evidence of a transition from semiconducting to a metallic state around 3000 K and 140 GPa. The possibility of a first-order phase transition has been studied with the best numerical techniques. However, a definite conclusion about such a scenario is still missing.

The dissociation transformation revealed by these studies in which molecular hydrogen transforms, not directly into a fully ionized plasma but first into a partially ionized atomic fluid, is also relevant to modeling the interior of giant planets such as Jupiter or Saturn. However, the situation there is more complex because hydrogen and helium coexist as main components. It is estimated that these two elements are at pressures of up to 4500 GPa, and temperatures up to 24,000 K in Jupiter, and about 1000 GPa and 10,000 K in Saturn. The planet is thought to consist of three main layers: an outer layer of molecular hydrogen and atomic helium, a middle layer of metalized atomic hydrogen and helium, and a rocky core compressed to as high as 104 GPa at the center of Jupiter. In Saturn, an internal energy source has been proposed, from demixing and gravitational separation of the hydrogen–helium fluid at pressures below 1000 GPa.

Conclusion

Almost four decades of progress in theoretical, computational, and experimental techniques have brought the study of the electronic structure of liquids from an initial pioneering stage to the present state where it is possible to investigate the electronic properties of liquids almost at the same level of accuracy than in the case of crystalline solids.

It is difficult to overestimate the role played by AIMD, although we have to recall that the underlying DFT has not yet reached a completely mature state (Burke, 2012). In particular, the case of strongly correlated systems remains an active research topic. Efficient application to the liquid state of alternatives to DFT like Diffusion Monte Carlo, domain-based local pair natural orbital coupled cluster, the time-dependent formulation of DFT, and the GW method (Per and Cleland, 2020), remains an active field of investigation.

Abstract

We consider the phenomenology of a liquid rapidly quenched below its melting point. The metastable state obtained is called supercooled liquid and its behavior shows many interesting and peculiar features. The supercooled liquid can be further quenched to approach the transition to the glassy state. Glasses are amorphous solids with a disordered structure, they are relevant in many applications. The glass transition takes place in a metastable region and it is characterized by a very interesting phenomenology. In approaching the glassy state supercooled liquids show a slowing down of the dynamics and a rapid increase of the viscosity of many order of magnitude. We will discuss how the interplay between thermodynamics and dynamical behavior in the metastable region represents a very challenging problem for statistical mechanics and experiments. As an example of a very important system we consider the supercooled liquid state of water. The experiments are limited by difficulties in avoiding crystallization. For this reason computer simulation has played a very important role in the study of supercooled water. This is still a topic of a large amount of research both for experiments and theories with many open questions.

Key points

- Consider substances kept liquid below the melting point to obtain supercooled liquids.
- Consider the thermodynamics and dynamical properties of supercooled liquids.
- Describe the transition to the glassy state.
- Consider the classification of glass formers materials in terms of fragile and strong materials.
- Describe the slow dynamics of the supercooled liquids in approaching the glass transition.
- Assume as an important example the case of supercooled liquid water.
- Show the peculiar behavior of water in approaching the glass transition with the presence of a second critical point connected to a fragile to strong transition.

Introduction

In the area of condensed matter physics the systems under study are composed by many interacting atoms. These systems are present in our life in different forms, for instance we are accustomed to see water at ambient conditions as a liquid, upon heating it becomes vapor (gas) and after some time in a freezer it becomes ice. Normally the phase diagram of a single component system is characterized by the three equilibrium phases gas, liquid and solid. The solid equilibrium phase is the crystalline structure. From the microscopic point of view in the gas and liquid phases the atoms are in disordered configurations, they move continuously while in the crystal the atoms are located on precise positions in the space. However in our everyday activities we have to deal sometimes with materials that are not in an equilibrium state. The most well known are the sheets of glass in our window panels. Glass is a particular state of matter, it is a solid characterized by a disordered arrangement of the atoms. For this reason the glasses are called amorphous solids to distinguish them from the crystalline solids. Glassy materials are not in equilibrium but they persist in their state for very long time and for this reason it is usual to consider the glassy state as metastable. It is important in physics to understand the phenomenon of transition from a liquid to a glass. In order to reach the glassy state from the liquid the substance must be kept liquid below its melting point upon cooling. Such liquid is called supercooled liquid. Experimental methods, theoretical approaches, and computer simulations gave important insight in studying the phenomenon. In experiments special

techniques can be applied to a system in the liquid phase to avoid the crystallization below the melting point. The supercooled liquid is an important metastable state of matter and its study sheds light on the mechanism of formation of glasses and on other relevant phenomena that are observed in different materials of interest in technological application, in biology and in medicine.

Overview of metastable states: From supercooled liquid to glass

The values of temperature, pressure and number of moles, considered as the external constraint variables, usually determine the state of a substance. According to Thermodynamics, equilibrium states are defined by the conditions of minimum of the appropriate thermodynamic potential for the given external constraints. For instance at constant pressure p , temperature T and fixed number of moles the thermodynamic potential to consider is the Gibbs free energy

$$G = U - TS + pV \quad (1)$$

where U is the internal energy, S the entropy and V the volume.

The lifetime of an equilibrium state is infinite and only changes in the external variables can induce a transition to another state. It is well known for instance that a liquid can be transformed in a crystal upon decreasing the temperature. The temperature of the transition changes by varying the pressure. The liquid and solid phases coexist along a freezing/melting line defined in the T, p plane.

Upon cooling the process of formation of the crystalline phase is not rapid in terms of microscopic time scales. It starts with the formation of a nucleus where the atoms are ordered in a regular pattern. In order to form a crystal the nucleus must diffuse and grow. But as long as the crystalline pattern grows, the viscosity increases slowing down the diffusion. The consequence is an increase of the relaxation time τ_{relax} to equilibrium. With a fast enough quenching procedure the crystalline growth can be frustrated and the system remains in the liquid state. Eventually with appropriate quenching rate the supercooled liquid can be driven in an amorphous solid state. The quenching rate necessary to bypass crystallization depends on the chemical composition of the material. For instance it can be estimated of the order of 10^{-2} K/s, for system like SiO_2 or GeO_2 and it increases up to 10^9 K/s for metallic glasses.

To understand why a glass can remain as such for a long time we must consider that below melting the free energy has a minimum at the stable crystalline state but it is possible under some conditions the existence of other local minima located at higher levels. If a local minimum is separated from the stable state by a very high barrier, see Fig. 1, the system remains trapped in the metastable state. To be more precise it results that the lifetime of the state is such that $\tau_{life} > \tau_{obs}$, where τ_{obs} is the typical observation time of experiments.

The transition from liquid to glass is not a conventional phase transition between equilibrium states, however as long as the condition $\tau_{life} > \tau_{obs}$ is satisfied it is possible to use thermodynamic concepts, as we will see below.

Many systems show a transition from the supercooled liquid to a glassy state. In a glass the atoms are not located in precise positions but the local arrangement of the atoms, called short range structure, sometimes resembles that of the corresponding crystal. The terms amorphous solid is often used as synonymous of glass. There are also systems, like water, where it is difficult to drive directly the supercooled liquid to the glassy state, the amorphous ice. Given the importance of water we will discuss its case later.

In Fig. 2 it is represented the behavior of the enthalpy $H = U + pV$ as function of temperature. This thermodynamic potential is the most used in experiment on melting that are performed at constant pressure since it gives a measure of the work required for changing volume. As usual in the liquid phase the enthalpy decreases at decreasing temperature and at the melting point T_m there is a change ΔH related to the latent heat of fusion (or solidification). If the system is maintained in the supercooled liquid state the

Fig. 1 Schematic representation of a possible Gibbs free energy profile below melting as determined by the system configuration. From the upper stable liquid state it is possible upon cooling to reach the crystal stable state but with a very rapid quench the system can be driven to a metastable state. The higher the barrier ΔG between the higher and the lower minima the more the lifetime of the metastable state is increased.

Fig. 2 Enthalpy change upon cooling. On the left T_m is the melting temperature. T_g is the glass transition temperature. On the right side the transitions to *Glass1* takes place at a higher temperature with respect to *Glass2* due to the different quenching rate.

enthalpy keeps to decrease as a continuous function. At the transition to the glassy state, $T = T_g$, it is usually observed a change in the slope and the enthalpy decreases in similar way as in the crystalline phase.

It has to be noted that while the melting temperature has a fixed value, since the liquid-glass transition does not occur between two equilibrium phases the glass transition temperature T_g depends on the quenching rate. By slowing down the cooling rate it is found a lower glass transition temperature. A schematic example is shown in the right side of Fig. 2.

So by slowing down the quenching rate it is possible to decrease T_g . Kauzmann explored the possibility of predicting an asymptotic glass transition temperature. He observed from the phenomenology that the entropy of the supercooled liquid decreases more rapidly than the entropy of the crystal and he deduced that it could exist a temperature where the entropy of the supercooled liquid could reach and cross the curve of the crystal entropy. The temperature T_K , that we call now Kauzmann temperature, is defined as the temperature where

$$S_l(T_K) - S_{cr}(T_K) = 0. \quad (2)$$

where S_l and S_{cr} are respectively the liquid and crystal entropy. Kauzmann realized that for $T < T_K$ the more disordered liquid state would have an entropy lower with respect to the ordered crystal. In order to avoid this paradox Kauzmann suggested that a crystallization would occur in approaching T_K . Estimations of T_K require extrapolations of experimental data well below T_g . The Kauzmann hypothesis has been widely discussed in literature. It has been suggested that the Kauzmann temperature would correspond to a limit of very slow supercooling process with the liquid attaining an ideal glass transition.

Dynamics of supercooled liquids

Diffusion

The motion of the atoms in a liquid is characterized by different regimes of diffusion. Each atom is surrounded by nearest neighbor but in the initial time it moves freely. This is called ballistic regime. After a period of time the atom starts to collide with the others and the diffusion enters in a more complex regime. This type of motion with frequent collisions is related to the old studies performed by the botanist Robert Brown in 1827 on the motion of pollen suspended in water. In 1905 Einstein reconsidered the work done by Brown and he developed a more general theory of the diffusion based on statistical mechanics. The diffusion of atoms can be studied by considering the displacement of an atom $r(t)$ from the initial position at $t = 0$. Since the motion is completely random the average on the time indicated with $\langle \dots \rangle$ will give $\langle r(t) \rangle = 0$. For this reason to study the phenomenon we must consider the mean square displacement (MSD). The average on the time obtained in experiments is replaced in the theoretical approach by the statistical mechanics average, realized by averaging on a great number of trajectories.

The MSD is one of the important quantities that connects directly our macroscopic measure to the microscopic behavior. Einstein introduced the diffusion coefficient D as a phenomenological parameter and he found that along each direction in the long time limit $\langle x^2(t) \rangle \rightarrow 2Dt$. So the MSD increases linearly with the time following in three dimensions the Einstein relation

$$\langle r^2(t) \rangle = 6Dt. \quad (3)$$

The diffusion of atoms in the liquid can be studied by experiments and simulations. It is observed that the diffusion is strongly determined by the thermodynamic conditions as represented in Fig. 3. In a liquid above melting after the ballistic regime for the frequent collisions the diffusion process enters in the Brownian regime described by the Einstein relation. From the long time slope the diffusion coefficient can be determined.

Upon supercooling it is observed a strong modification. After the ballistic regime it appears a plateau. Below melting, even if it is avoided the transition to a crystalline structure, there is a formation of a cage of nearest neighbors around each atom. At variance

Fig. 3 Mean square displacement as function of time for decreasing temperatures.

with crystal the cage persists for a short time, but the region of the plateau corresponds to the period in which the atom is trapped in the cage. This is called cage effect. After a certain amount of time the cage relaxes and the diffusion starts again in the Brownian regime. The length of the plateau increases upon decreasing temperature.

Fragile and strong liquids

Related to the diffusion in liquid it is also the viscosity, indicated as η . The viscosity is intended as the friction due to the collisions that slows down the velocity of the moving particles. An higher viscosity reduces the diffusion. For spherical particles of radius r_0 they are related through the Stokes-Einstein formula

$$D = \frac{k_B T}{6\pi r_0 \eta}. \quad (4)$$

It is well known that a large increase of the viscosity is observed in approaching a transition to a solid state. By collecting the experimental measures of a large number of glass formers Angell found evidence that the viscosity increases of many order of magnitude in the supercooled liquid and it reaches a common value at the glass transition. He proposed as definition of T_g the temperature at which the viscosity η is found to be

$$\eta = 10^{13} \text{ poise} \quad (5)$$

By considering the behavior of the viscosity in approaching the common value at T_g Angell introduced a precise classification of the glass former materials. Two types of phenomenology are found, as shown schematically in Fig. 4.

There are systems, classified as strong glass formers, where $\log(\eta)$ increases linearly. This behavior is called *à la* Arrhenius and it is the most simple to explain

$$\eta(T) = \eta_0 e^{E_A/k_B T} \quad (6)$$

where E_A is the activation energy and η_0 is the limit at high temperature. In an Arrhenius process it is considered that a particle can move by overcoming a potential barrier with E_A the energy required.

In the category of strong liquids there are systems like SiO_2 and GeO_2 . This glass formers are characterized by a tetrahedral local order that does not change going to the glassy state. As a consequence it is found a small change in the specific heat across T_g .

Other systems, called fragile, show a so called super Arrhenius behavior. η approximately follows the Vogel-Fulcher-Tamman (VFT) phenomenological formula

$$\eta = \eta_0 \exp \left[\frac{BT_0}{T - T_0} \right] \quad (7)$$

where T_0 is an hypothetical temperature below T_g where η would diverge. The parameter B is related to the degree of fragility, since smaller values of B correspond to higher fragility.

Fragile liquids, as for instance glycerol or ethanol, show a complete change in their local structure with a large change in the specific heat across T_g . The motion of the particles in fragile liquids upon supercooling is determined by a sequence of overcoming barriers in a configurational space more complex with respect to the case of strong liquids.

Fig. 4 Behavior of $\log \eta$ as function of T_g/T : strong behavior as Eq. (6), fragile behavior as Eq. (7).

Slow dynamics

The thermodynamic conditions determine the macroscopic density of the fluid ρ_0 . At the microscopic level the atoms move continuously. The local density of the particles $\rho(r, t)$ fluctuates around the equilibrium value ρ_0 . During fluctuations the particles usually move from a zone at higher density to a zone with lower density to partially restore the equilibrium. In order to study more in details the density fluctuations we have to consider that the microscopic fluctuation in a position r at time t

$$\delta \rho(r, t) = \rho(r, t) - \rho_0$$

is correlated to the fluctuation in another position r' at a different time t' of another or the same particle. In the study of the diffusion we follow the motion of a single particle. In similar way we can follow the fluctuations of the density of a single particle $\rho_s(r, t)$ and look how the fluctuation at a certain time and position is related to a previous fluctuation in a different position and time. For this purpose we can introduce the statistical average of the product of the single particle fluctuations

$$C_s(r - r', t - t') = \langle \delta \rho_s(r, t) \delta \rho_s(r', t') \rangle \quad (8)$$

This is the self correlation function that in an homogeneous system depends from the differences $r - r'$ and $t - t'$.

The Fourier transforms of density correlation functions are accessible to neutron scattering experiments. By considering the Fourier transform of the single particle density fluctuations $\delta \rho_s(k, t)$ it is possible to define the self intermediate scattering function as

$$F_s(k, t) = \frac{1}{N} \langle \delta \rho_s(k, t) \delta \rho_s(-k, 0) \rangle \quad (9)$$

From its definition $F_s(k, t = 0) \rightarrow 1$.

In liquids above melting the behavior of the $F_s(k, t)$ is represented in Fig. 5 (black curve) for a wave vector $k = k_0$ where $k_0 \approx 2\pi/r_0$ with r_0 the nearest neighbor distance between the atoms, the most interesting distance to explore for this phenomenon.

After a short period corresponding to the ballistic regime, the function decays exponentially with the Debye equation

$$F_s(k, t) = e^{-t/\tau} \quad (10)$$

where it is introduced the relaxation time τ , that measures the time needed to the system to reach the equilibrium. So τ is connected to diffusion and viscosity. In particular it results that

$$\tau = \text{const} \frac{T}{D} \propto \eta \quad (11)$$

according to Eq. (4) τ is proportional to η .

In the supercooled liquid it is observed a change in the behavior of $F_s(k, t)$ due to the cage effects. As shown in Fig. 5, a plateau appears in correspondence to the period in which the atom is trapped in the cage. The long time decay is modified in the form of a stretched exponential

Fig. 5 Behavior of $F_s(k_0, t)$ for a liquid above melting and for a supercooled liquid. In the normal liquid (black curve) after the ballistic regime the function decays exponentially. In the supercooled liquid (red curve) after the ballistic regime the function shows a plateau and it decays with the KWW function.

$$F_s(k, t) \approx e^{-(t/\tau)^\beta} \quad (12)$$

where it is found that the exponent $\beta < 1$. This type of decay is called Kohlrausch-Williams-Watts (KWW) function. The relaxation time τ increases of orders of magnitude with decreasing temperature with a different behavior expected for fragile and strong liquids since from Eq. (11) $\tau \propto \eta$.

The dynamical behavior of supercooled liquids has been studied and interpreted by several theories and models.

One of the most famous theoretical approach is the Mode Coupling Theory for the evolution of glassy dynamics (MCT). The MCT is a microscopic theory that provides a unified description of the dynamical properties of supercooled liquids. The cage effect and the long time decay of the correlation functions are derived from first principles starting from the only input of the static structure of the liquid. The glass transition is interpreted in terms of a transition from an ergodic regime where the system can reach an equilibrium state after the cages are dissolved to a non ergodic regime where the dynamic of the liquid is arrested. In particular the plateau in both the case of the diffusion and the dynamic correlation functions extends to infinity. The crossover would take place at a specific temperature T_C . The relaxation time τ introduced above will become infinite with a power law

$$\tau \sim (T - T_C)^{-\gamma} \quad (13)$$

where γ is an exponent related to the microscopic properties of the liquid. According to MCT, by considering Eq. (11) the diffusion constant goes asymptotically to zero for $T \rightarrow T_C$. In summary the MCT predicts the glass transition in terms of an ideal ergodic to non ergodic cross over taking place at a temperature T_C that results higher with respect to the conventional glass transition temperature T_g . The MCT predictions can be tested by experiments in terms of asymptotic behavior of the diffusion and the long time decay of the density correlation functions.

Often MCT works only in the regime of mild supercooling where extended structural relaxation drives the system toward ergodicity. In the deep supercooled region for many glass formers when the structural relaxations are frozen hopping (activated) processes restore ergodicity. In this regime the system explores the valley of the free energy landscape.

Adam and Gibbs connected the relaxation to equilibrium of supercooled liquid in the deep supercooled regime with the entropy of the system. In particular they consider the role of the configurational entropy S_c that is approximately identified as the difference between the liquid entropy and the crystal entropy. S_c is related to the number of available glassy states at the given temperature and pressure conditions. Adam and Gibbs found for the relaxation time the equation

$$\tau \propto \exp \left[\frac{\alpha}{TS_c(T)} \right] \quad (14)$$

In the supercooled liquid approaching the glassy state S_c decreases, as consequence of the decrease of the possible configurations for the system. S_c can be derived from phenomenological observations of quantities like the specific heat in approaching the glass transition, in particular the configurational part of the heat capacity can be approximated as proportional to the inverse temperature

$$C_c \approx \frac{c}{T}, \quad (15)$$

this can be integrated to obtain S_c . By assuming that it exists a temperature T_0 for which $S_c(T \rightarrow T_0) = 0$ the configurational entropy can be calculated as

$$S_c(T) = \int_{T_0}^T \frac{c}{(T')^2} dT', \quad (16)$$

and substituting in Eq. (14) we obtain

$$\tau = \tau_0 \exp \left[\frac{BT_0}{(T - T_0)} \right]. \quad (17)$$

the VFT formula introduced before as obtained from experimental data.

Supercooled water

Among all glass formers water singles out because its behavior is characterized by anomalous properties in comparison with other substances. The most well known anomaly is the fact that ice is less dense than liquid water. Upon decreasing temperature the density of liquid water increases as usual but at a temperature of 4 °C at ambient pressure the density starts to decrease. The change of slope of the density vs. temperature defines a temperature of maximum density (TMD). The line of the TMD as function of pressure extends just above the melting line. At melting it is found that the density of the crystalline phase ρ_{crys} is less than the density of ρ_{liq} . The reason is connected to the particular structure of liquid water and ice. The structure is based on the formation of hydrogen bond (HB) between water molecules. As shown in Fig. 6 the water molecule is formed by the bond of an oxygen and two hydrogens. In the H_2O molecule the oxygen remains with two lone pairs of electrons and it has an effective negative charge while each hydrogen in the bond with the oxygen results to have a positive charge. The negative lone pair can attract the positive hydrogen of another molecule to form the so called hydrogen bond (HB). If enough molecules are present each molecule results to be connected to other four as shown in the figure. The pentamer shown in the figure is the nucleus of the crystalline structure of ice.

No man's land and glassy states of water

Because of its strongly stable pentameric structure water has a very strong tendency to crystallize. Even the ice cubes contained in our freezer are polycrystalline and made of small single crystal grains of hexagonal ice, which is the stable state of ice at ambient pressure. As a consequence the quenching of liquid water below melting to enter in the supercooled region is more difficult than in other liquids. Beside, the presence of impurities favors the formation of ice nuclei and the crystallization. By appropriate experimental techniques the concentration of impurities can be restricted, in this way the temperature of the onset of crystallization can be reduced. By extrapolating, it is possible to define for any pressure a limiting value for the temperature of supercooling. This temperature is called the homogeneous nucleation temperature, indicated with T_H . The curve of T_H as function of pressure has been for many years the lowest limit for performing experiments on supercooled water. In particular they were left without explanation the experimental observations of the anomalous increase of quantities like the isothermal compressibility K_T and the isobaric specific heat C_p upon supercooling in approaching the T_H line, as shown in Fig. 7.

This type of strong increase of K_T and C_p is observed when a liquid approaches the liquid-gas transition as a precursor effect of the divergence of those quantities at the critical point.

New more recent methods have been successful in supercooling below the homogeneous nucleation temperature. Amorphous ice systems can be obtained by overtaking the region of supercooled liquid for instance by rapid quenching directly from the vapor. Two different amorphous ice states have been found, see Fig. 8. At lower pressure the low density amorphous (LDA) that coexists with the high density amorphous (HDA) at higher pressure. The coexistence line is close to 200 MPa and a first order transition is observed between the two states with changes in volume and enthalpy. LDA and HDA are characterized by different local structures. LDA shows a more ordered short range structure similar to a tetrahedral network, while in HDA the molecules are arranged in a more disordered structure where the tetrahedral short range order is lost.

Fig. 6 (a) water molecule, (b) H-bond between two molecules, (c) HB between four water molecules.

Fig. 7 Isobaric specific heat and isothermal compressibility of water upon supercooling.

Fig. 8 Phase diagram of supercooled liquid water and amorphous ice states. The LDA/HDA coexistence evolves in the LDL/HDL coexistence in the no man's land, where it would be present a liquid-liquid critical point (LLCP).

LDA and HDA undergo a glass transition at around 136 K, above 136 K it is found an high viscous liquid that at ambient pressure crystallizes in a cubic ice at 150 K. In analogy with the definition of the homogeneous nucleation line T_H it is possible to define a temperature of spontaneous crystallization T_X . The lines of T_H and T_X as function of pressure delimit from above and below respectively the so called *no man's land*, where supercooled water is very difficult to study by experiments.

The second critical point and two forms of liquid water

In the *no man's land* region recent extensive computer simulations and experiments gave access to a rich phenomenology, see Fig. 8. The LDA and HDA upon increasing temperature above the line T_H undergo a transition to two forms of liquid, called for analogy with the glassy states, low density liquid (LDL) and high density liquid (HDL). LDL and HDL keep local structures very similar to the corresponding glassy states. The great difference is that the coexistence line LDL/HDL would terminate in a critical point, called liquid-liquid critical point (LLCP), hypothesized by Poole, Sciortino, Essmann, and Stanley in 1992. On the basis of results of

computer simulations and extrapolation of experiments the LLCP was estimated to be in the *no man's land* at around 220 K at a pressure of 100 MPa approximately. The presence of this second critical point could explain the experimental observations of the anomalous increase of the isothermal compressibility K_T and the isobaric specific heat C_p in approaching the border of the *no man's land*.

It is found that the LDL configuration is characterized by a lower entropy and energy with respect to the HDL structure. In LDL in fact the short range order is similar to the tetrahedral arrangement observed in ice. In the HDL structure instead there is a collapse of the tetrahedral structure making possible to reach an higher density.

We have already seen that in a fluid the microscopic fluctuation of the density in a position r is correlated to the fluctuation in another position r' . In normal thermodynamic conditions the density fluctuations in different points are correlated in a range determined by the correlation length ξ . Upon approaching the critical point the correlation length increases and it diverges at the transition. This induces the large increase and the divergence of K_T and C_p since they become proportional to powers of ξ .

As in the case of the liquid-gas transition also for the LLCP we can consider more in details the behavior of the system in approaching the critical point from the single phase region. It is found that both the isothermal compressibility and the specific heat start to show maxima along lines that finally collapse on the so called Widom line, the locus of the maxima of the correlation length that extends from the critical point toward the single phase region. In the case of the liquid-gas transition the Widom line close enough to the critical point separates liquid-like states from gas-like states in the single phase region.

In computer simulations the Widom line can be located by searching the maxima of the specific heat or the isothermal compressibility in the single phase region. At the crossing of the critical point the Widom line will be connected to the coexistence line in the two phase region. We will show below that the Widom line has an important role in the classification of the dynamical behavior of supercooled water.
